Keep the bowels thoroughly open.

Keep the alimentary canal as aseptic as possible.

Give good nourishing food—that which the patient will readily assimilate.

Give plenty of water both by the mouth and rectum.

Use the best intestinal antiseptic known.

Never give opium.

Never give phenacetin or acetanilid.

Give strychnia as indicated.

If this plan is followed you will rarely have a death from typhoid fever.

1300 W. Fourth St.

DIET IN TYPHOID FEVER.

Read by title in the Section on Practice of Medicine at the Forty-eighth Annual Meeting of the American Medical Association at Philadelphia, Pa., June 1-4, 1897.

BY FREDERICK C. SHATTUCK, M.D.

JACKSON PROFESSOR OF CLINICAL MEDICINE IN HARVARD UNIVERSITY.
BOSTON, MASS.

When typhoid fever kills it does so either by perforation or exhaustion, the proportion of the former being estimated at 5 to 10 per cent. The main factors in producing the exhaustion which causes the death of at least nine-tenths of the fatal cases are toxemia, continued fever, diarrhea and vomiting and intestinal hemorrhage. The heart is ordinarily the best index of the presence and degree of exhaustion, and the most frequent serious pulmonary complication, hypostasis, in its various forms, degrees and consequences is the direct outgrowth of the cardiac weakness. Moreover typhoid fever is not short and sharp like pneumonia, but of long course, and usually attended with decided, often with very great wasting of the muscular and fatty tissues.

Most of us are agreed that we are not as yet acquainted with any therapeutic measures which will either abort or very materially shorten the course of the disease. We are, I think, unanimous in believing that husbanding the strength from the start through skilful nursing, the judicious use of water externally and internally, and the supervision of a wise attendant on the watch for and prepared to meet such indications as may arise, materially modifies the course of the disease and lessens its mortality. If what I have assumed to be facts be really facts, the question of diet must be a very important one in the management of typhoid fever. It is through the food which is assimilated, not through that which is merely put into the stomach, that we seek to limit the tissue waste while the process is active, and also try to land the patient on the low shore of convalescence with as much of his property as may be; for the recovery of his property is a necessary preliminary to the attainment of the high table-land of full health.

Under the old doctrines as to inflammation fever was an unfailing indication for depletion; directly by venesection, pukes, sweats and purges; indirectly by starvation. Indiscriminate direct depletion is now a thing of the past, and since the time of Todd the fact has gradually been more and more clearly recognized that the febrile state is often an indication for more, rather than less, nourishment, with selection as to quality rather than diminution as to quantity. In the shorter essential fevers a few days' starvation can not do much harm, and may even be of great service with a certain class of patients. But suppurative fever, for instance, whether of tubercular or other origin, especially if chronic, we feed to the largest limit; and we do this because we treat the condition and not the disease, individualizing our cases. Since our knowledge of gastric chemistry has been enriched by the adaptation of the soft catheter to another hollow viscus at the opposite extremity of the abdomen, a more complete explanation has been afforded for the fact which we knew by practical experience before, that gastric digestion is often weakened in the febrile state. But the same practical experience teaches us that it is not always so, or very materially so, and when theory and practice conflict the former must prevail. Have we not fully escaped from the domination of the old doctrine as to the lowering treatment of inflammation, or are there valid reasons why we should be less bold in feeding our typhoid patients than our chronic febrile consumptives? Three such reasons deserve special consideration. In the first place, typhoid is far more frequently a self-limited disease than is phthisis; but the fact of self-limitation does not seem to me to warrant us in underfeeding, for the less the patient loses the less does he require to regain. In the second place, typhoid has constant intestinal lesions which may bleed or perforate and which may be accompanied by a general catarrhal state of the intestinal tract. I may perhaps add here that diarrhea is not nearly as constant a symptom in typhoid fever as the books lead students to believe. In at least 50 per cent. of my hospital cases no diarrhea was present at any time. We must therefore have reference to the local intestinal lesions as well as to the general state. In a disease of such long course, it is impossible to prevent accidents by putting the bowels in splints, even if it were desirable to do so. More or less peristalsis must go on, and waste matter must pass over the ulcerated surfaces; and how deep or extensive the ulcerated surface may be in any particular case no symptom or group of symptoms enable us to measure. Hence, it seems rational, quite apart from the fever, to withhold from the diet any articles the residue of which is liable to irritate either the mucous membrane in general or the ulcerated portion in particular. This would seem a fair explanation for the popularity of milk as a diet for typhoid, containing as it does a large proportion of water and every principle necessary to nutrition so combined as to make relatively small demands on the digestion of most persons, and leaving a residue which, though notoriously large, is not mechanically irritating. The objection to milk is that it is repugnant to a few persons and becomes either repugnant or monotonous to a considerable number sooner or later. It is not necessary here to specify the many expedients which may and often must be resorted to to overcome this objection, and in some cases to render it digestible whether palatable or not. Milk is likely to maintain a very important, perhaps leading place in the diet of typhoid as well as of other diseases and conditions. For a number of years I adhered as strictly as possible to an exclusively milk diet in typhoid fever until at least a week had elapsed from the date of the first normal evening temperature. I closed my ears to the clamors of adults, and my eyes and heart to the tears of children, as I now believe unnecessarily. Thirdly, it was only comparatively recently the general opinion of the profession that relapse is or may be due to errors in diet. I well remember the time when a fresh access of fever led my teachers and me to carefully inquire into the kindness of officious friends. It was often proved that forbidden fruit actually or metaphorically had been brought in by a visitor, and this was an entirely satisfactory explanation. When proof could not be had the fact of relapse was strong presumptive evidence of sin. We know better now, and while we recognize that errors in diet may produce fever, as may fatigue or excitement in convalescence from any severe disease, we do not believe that they can start up a fresh invasion of bacilli from within. One of the things which set me thinking on this question of the diet in typhoid was the favorable course run by several acute febrile cases for whom I ordered a full diet because they were weak; believing at the time of so doing that typhoid could be excluded, but being forced to the conclusion later that only typhoid fever could explain the whole course of the disease. These patients did perfectly well, were happier and convalesced more rapidly than my recognized typhoid cases fed exclusively on milk. For five years now, I have been enlarging the diet of my typhoid cases and have seen no reason to regret this course, but on the contrary found cause for satisfaction.

During the twelve years, 1886 to 1897 (both inclusive) 380 cases of typhoid fever have come under my personal care in the Massachusetts General Hospital. From 1886 to 1893, 233 cases were treated under a milk diet with a mortality of 10 per cent. From 1892 to 1897, 147 cases have been treated under a much more extended diet with a mortality of 8.1 per cent. I know well the liability to reach false conclusions in reasoning from too small figures in a disease like typhoid fever. And it is also true that water has been used more efficiently of late than in former years. But I can see nothing in my figures to contravene my observation that an enlarged diet has not been injurious. I would not be understood as advocating an indiscriminate diet. My plea is simply for treating the patient rather than the disease; for feeding him with reference to his digestive power rather than solely or mainly with reference to his fever; for the view that the danger of accidents from the local intestinal ulceration is not increased by allowing him to partake of articles which leave no irritating residue, and which cautious trial shows are digested without disturbance or discomfort. At one end of the scale are the cases with such irritability or weakness of the stomach as to lead to the unfortunate term gastric fever, or those with pronounced diarrhea and undigested food in the stools; at the other end are those more numerous cases with clean tongue and a desire for food. Between the two is every gradation. The life of the former may depend on the skill and ingenuity of the doctor, assisted by the intelligent devotion of the nurse. The comfort and the duration of disability of all others may be materially modified for good by careful study and wise individualization of our cases. A long list of permissible articles from which selection can be made for different cases, and for the same case at different times under varying circumstances can be given. That which I append makes no claim to completeness, but is meant merely to be suggestive and illustrative.

TYPHOID DIET.

1. Milk hot or cold, with or without salt, diluted with lime water, soda water, apollinaris, vichy; peptogenic and peptonized milk; cream and water (*i.e.*, less albumin), milk with white of egg, slip, buttermilk, koumyss, matzoon, milk whey, milk with tea, coffee, cocoa.

2. Soups: beef, veal, chicken, tomato, potato, oyster, mutton, pea, bean, squash; carefully strained and thickened with rice (powdered), arrowroot, flour, milk or cream, egg, barley.

3. Horlick's food, Mellins' food, malted milk, carnipeptone, bovinine, somatose.

4. Beef juice.

5. Gruels: strained cornmeal, crackers, flour, barley-water, toast-water, albumin, water with lemon-juice.

6. Ice-cream.

7. Eggs, soft boiled or raw, egg-nog.

8. Finely minced lean meat, scraped beef. The soft part of raw oysters. Soft crackers with milk or broth, Soft puddings without raisins. Soft toast without crust. Blanc mange, wine jelly, apple sauce and macaroni.

CAN TYPHOID FEVER BE ABORTED—THE ANSWER.

Read in the Section on Practice of Medicine, at the Forty eighth Annual Meeting of the American Medical Association, held at Philadelphia, June 1-4, 1897

BY J. E. WOODBRIDGE, M.D.
CLEVELAND, OHIO

There are departments in medicine of which it may be truly said that "reasoning is deceptive;" in which actual experience gives the only light by which our footsteps may be guided; in which the clinical experience of a single observer, who has been wisely taught and has wisely followed the teaching, is of greater value as evidence of the justness of a conclusion, than is the subtlest reasoning of the most astute logician. This is eminently true of the subject which is presented for your consideration today.

The question which forms the title of this paper can be correctly and forcefully answered only by those who can speak from bedside experience.

The subject has already been fully and ably discussed, every imaginable argument has been adduced to establish a negative, but the force of most of these has already been broken by the silent footfalls of advancing. science.

The effect of the antitoxins of diphtheria, the bubonic plague and other diseases, and the discovery of Laveran, that ague is a specific infection in which every drop of blood is invaded by a living organism, coupled with the well known fact that a single dose of one of the least harmful of drugs will not only abort an attack of malaria, but will effectually disinfect the blood circulating in every part of the body, from the tip of the finger to the ball of the toe, emphatically negatives all the arguments that have been advanced to prove that the course of the specific infections can not be interrupted, and especially that typhoid fever will run its course in defiance of all medication; yet these dogmatisms have been quoted, repeated, reiterated and applauded, as if they contained the very essence of all the wisdom of all the ages, past, present and future. They are *not true*, but the declaration that typhoid is a curable malady has been for years and is yet nearly always greeted with such "acrimonious and vituperative dissent" that it should not surprise us if the bravest men were to hesitate before reporting cases of "aborted typhoid fever," well knowing that such reports would expose them to the ridicule, invective and brutal sarcasms of those who, lacking their knowledge of the power of antiseptic medicine, receive with derision every allusion to the curative treatment of the specific infections.

No wonder then that physicians who cure these diseases are afraid to publish their reports; no wonder that some physicians who promised to send me the clinical histories of their cases have never done so; no wonder that some of my friends, who kindly sent valuable statistics, with permission to use their names in this report, afterward withdrew their consent. The wonder is, that under the circumstances any physician should have had the courage of his convictions and should have dared to allow me to use the data which are here presented. It was, therefore, with extreme diffidence that I wrote to a few physicians who had previously written to me for specific information about this method of managing typhoid fever, asking them for reports of their cases for publication.

But the medical profession it seems is equal to any emergency and there is no demand that can be made upon it in the name of suffering humanity, which it does not immediately supply, as the generous and noble responses that are embodied in this report clearly prove; and despite the fact that the ordinary difficulties which beset the gathering of statistics on any new method of treatment have been enormously augmented for the abortive treatment of typhoid fever by the sharp criticism to which it has been subjected, I present herewith the statistics of 6,911 cases of typhoid fever that have been treated by the method I have advised, with quotations from the reports of a few of those physicians who have not only had the intelligence to institute scientific treatment and with it to abort the disease, but have also had the heroism to brave the innuendoes and criticisms of the molders of medical thought, and have supplied the data which must unequivocally place this heretofore most terrible sickness among the curable diseases. In signing these reports they have braved dangers as real as those which confront the soldier on the battlefield, and in speaking out in advocacy of the abortive treatment of typhoid fever they have jeopardized their professional careers, but they have exhibited the true nobility of their characters.

At the last meeting of this ASSOCIATION, the method of managing typhoid fever, which is dealt with in these reports, being under discussion, certain arguments were advanced with the manifest object of detracting from the value of the treatment by showing that the typhoid fever of this country and during recent years, is not the same disease that prevailed here twenty or thirty years ago or that is today so much dreaded in foreign lands. These arguments must have sounded strange to the ears of scientists who regard the bacillus of Eberth as the cause of the disease and who would naturally expect a given cause to produce a given effect under like circumstances. These arguments, aside from being unscientific, are in conflict with well known facts. For example, from 1864 to 1869 there occurred in the Boston City Hospital 152 cases of undoubted typhoid fever, 21, or 13.81 per cent. of which died, while the duration of the illness of those that recovered was 24.25 days. In St. Bartholomew's Hospital, London, 1860 to 1864, there were 244 cases of typhoid fever treated, with 27 deaths, or 10.06 per cent., while in the same hospital during the five years preceding the opening of the discussion of this subject in this Society (1893), 406 cases were treated, with 54 deaths, a death rate of 13.2 per cent. In the Buffalo General Hospital during the years 1892-3-4 (the only report to which I have access at present), 271 cases were treated to a finish with 47 deaths or 17.34 per cent. In the St. Louis City Hospital, during the years 1890 to 1893, there were treated 353 cases with 73 deaths, or a death rate of 20.68 per cent. During the years 1889 and 1890, there were treated in the Providence Hospital, Washington, 72 cases, of which 23 died, a death rate of 31.94 per cent. "Murchison places the death rate from this disease at 17.45 per cent., which is perhaps none too high for this city (Washington) during the time mentioned (July 1 to Oct. 31, 1895)." (Dr. Kober in Report of Health Office District of Columbia, 1895.) It is well known that a few other hospitals have reported lower death rates in a few instances and it is frankly admitted that these numbers are too small to eliminate possible errors, or to constitute a safe basis upon which to found exact conclusions, but so too are those from which are obtained the marvelously low percentages so vociferously acclaimed by a few enthusiastic advocates of cold water. They are large enough, however, for the purpose for which they are introduced—not to antagonize any particular method of managing the disease, but to prove that typhoid fever in this closing decade of the nineteenth century has lost none of its old-time virulence and intractibility; that it is still man's most insidious and relentless foe, running as tedious and obstinate a course to as certain death today as it did forty or fifty years ago.

The grave character of typhoid fever being proven we are confronted by several important questions: Can the disease be aborted? Can its course be interrupted? Can its death rate be lowered? Can its grave symptoms be ameliorated? Can relapses be prevented? Can complications be averted? In other words, is typhoid fever amenable to medical treatment? For answer I submit the following reports and in making the estimation of the value of the statistics, I beg you to remember that the physicians who have presented them were applying a method which was not only new to them, but which embodied practices that so far contravened all accepted theories, that many hesitated and did not dare, all at once, to throw away the old and fully adopt the new plans.

FRANCIS M. GREEN, M.D., Lexington, Ky., May, 1897:—I have treated in all thirty cases and without a single death. I aborted the disease in several cases, the temperature reaching normal by the seventh to ninth day. In the JOURNAL some time since I alluded to the ignorant and unjust criticism of the method. It is unfair in its enemies to cry out against our diagnosis without having first tried the treatment in cases which they themselves have pronounced typhoid fever. It is sufficient that the treatment will prove successful in a large majority of cases when commenced early.

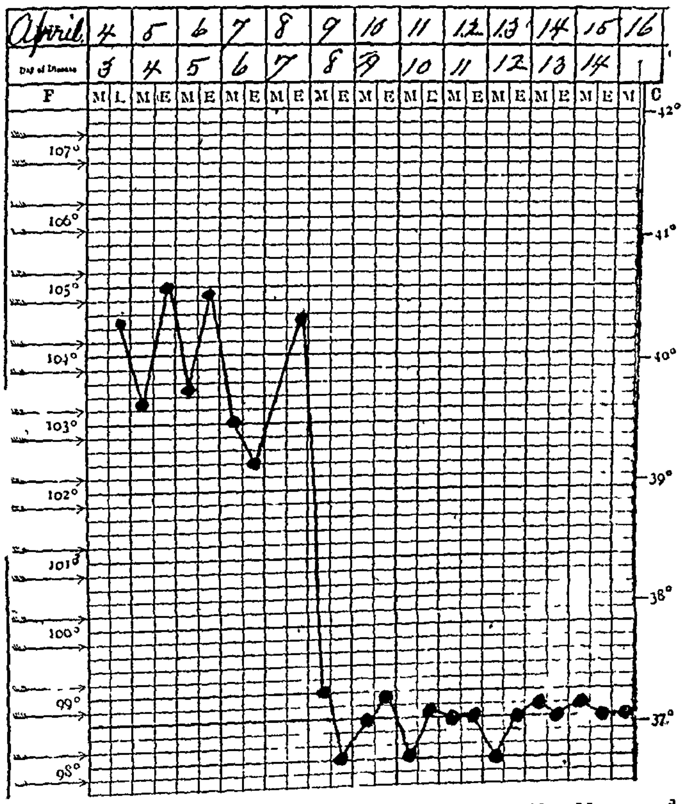
WILLIAM M. WRIGHT, M.D., Huntington, Tenn., May, 1897:—I approach a case of typhoid fever now with more confidence than ever before, and I attribute it to your method of treatment. To say that I am highly pleased at being able to make favorable mention of your method to physicians with whom I come in contact but puts it lightly. I tell them it is now the *sine qua non*. I am an unqualified advocate of and enthusiastic believer in the virtue of this method.

WALTER N. SHERMAN, M.D., Merced, Cal., May, 1897:—I also use your tablets with splendid results in many other diseases in which I think intestinal antiseptics are indicated.

SAMUEL W. HOVER, M.D., Fayette, Ohio, May, 1897:—I am sorry I can not give you a fuller report of my cases, but if I had any number of cases of typhoid fever I should use your treatment on every one. My cases have all done so much better under your treatment that I have practically all the field in this neighborhood and for all ailments. My worst case was an old lady aged 71 years and she had a very bad attack with all characteristic symptoms of the disease. No one thought she could live. I broke the fever in nine days and she made a rapid recovery. Six cases.

CARL BONNING, M.D., Detroit, Mich.:—I treated only two patients suffering from typhoid fever by your method. The first was an old lady nearly 60 years old, who was treated according to your method from the beginning. This was a mild case of true typhoid fever which ran its usual course of twenty-one days, with good recovery. The second case was a boy 14 years old, treated by your method from the first day. The symptoms became worse from day to day, temperature rising constantly and going up to 105 degrees F.; evacuations very frequent. On the ninth day a severe hemorrhage of the bowels set in, when I stopped your treatment at once, as I could not help but think that the treatment was the cause of his early and severe hemorrhage. The boy finally recovered under different treatment, though he was confined to his bed for six weeks more. Since then I have not given your treatment another trial.

HENRY CLAY DALTON, M.D., St. Louis, Mo., May, 1897:—I have treated eleven cases by the Woodbridge method, in fact all cases that I have had since I have commenced the treatment, because I certainly would not now treat that disease by any other method. All the patients recovered. None of the cases had any complications or sequelæ. With the exception of one case the tendency of the fever was to steadily abate. In the exception referred to the temperature became higher for two days after the commencement of the treatment, in fact the temperature increased two or three degrees. At the end of the second or third day it fell to about 102 degrees and in less than a week was entirely gone. In none of my cases was there delirium or tympanites. Dr. Simon Pollak of this city, at my suggestion, treated his son after your method. He was delighted with the treatment. I feel that you have a grand treatment of the disease and that it is the duty of every physician to use it. Certainly up to the present time there is no remedy which approaches it in efficiency. My experience is somewhat limited, but in the cases in which I have used it patients have gotten along most comfortably and the disease has been cut short. Eleven cases: no deaths.



Dr. Wm. H. Arthur, Fort Myer, Va. Patient John L., Fort Myer, aged 15 years; admitted to hospital April 4, 1896; diagnosis, typhoid fever. Previous history: Patient treated for intermittent fever for three days. April 4 and 5 delirium continued, quinin stopped, resisted all treatment. April 6, modified Woodbridge treatment commenced. Patient slept all night. April 7, no delirium. April 8, guaiacol added. April 12, all treatment stopped, liquid diet. April 14, ordinary diet resumed. Modified Woodbridge treatment consisted in multiplying dosage and dividing intervals by four. Patient's sleep never disturbed, but treatment resumed immediately upon awakening. Guaiacol carbonate was not on hand at first. It was procured and added on April 8. Persistent delirium of a very obstinate and exhausting kind was unaffected by chloral. Disappeared as soon as evacuations of bowels became free and frequent.

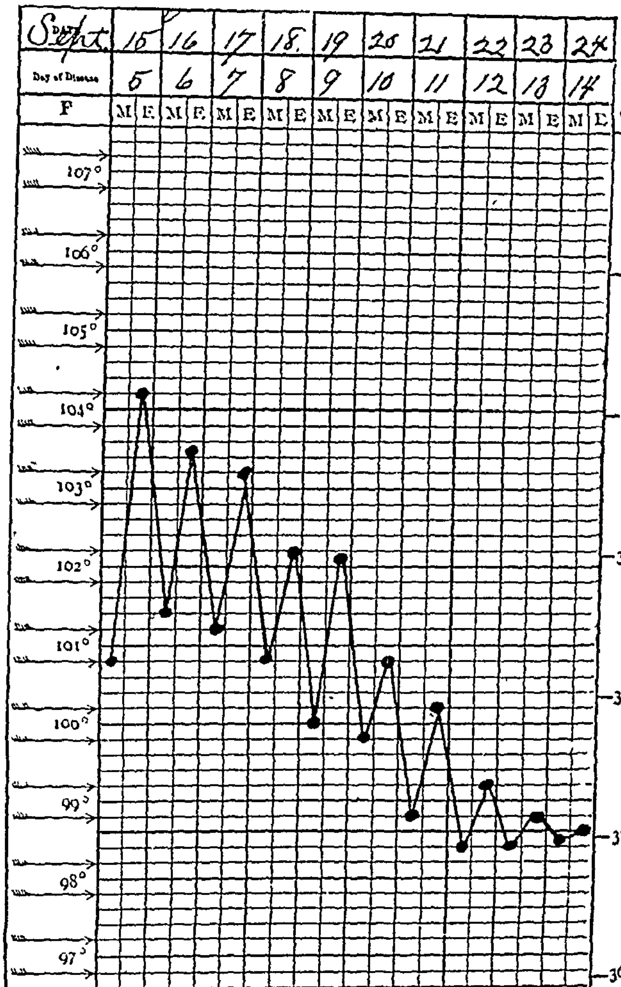
J. W. R., M.D., Missouri, May, 1897:—I think there is nothing like "Woodbridge treatment for typhoid fever." I have had the best results in every instance, with no deaths.

CHARLES S. JAMES, M.D., Centerville, Iowa, May, 1897:—I have been using the Woodbridge treatment for a considerable length of time with very satisfactory results.

BENJAMIN MOSBY SMITH, M.D., Davis, W. Va.:—I have the first case to lose since I adopted your treatment two years ago. The great trouble is physicians do not use the treatment as they should or as directed. I am with you heart and soul and feel certain it is the only sure treatment we have now.

EDWIN O. BOARDMAN, M.D., Overton, Neb., May, 1897:—I have treated thirty-six cases by your method. The first ten cases were not so successfully treated as were the later ones, because of two facts: 1, the medicines were not properly prepared; 2, they were not properly given. Since then I have used the tablets prepared by P. D. & Co., without a single death, my two deaths occurring among the first ten. One of these was complicated with an old heart lesion—a woman 45 years old; the other a boy of 8, died of purpura hemorrhagica ten days after the subsidence of the fever.

FRANK C. MYERS, M.D., Kalamazoo, Mich., May, 1897:—I have been very much pleased with your treatment and have used it faithfully for two or three years, in fact I was the first to use it in this city. I have read two or three papers in its favor at our Kalamazoo Academy of Medicine.



Dr. D. F. Manning, Marshall, Mo. J. N., aged 45. Diagnosis, typhoid fever.

ROBERT J. HILL, M.D., St. Louis, Mo., May, 1897:—I have so thoroughly adopted your plan of treating typhoid fever and typhoid conditions that, judging from my past experiences, I have no more typhoid. I do not allow the disease to go so far but that when I meet a case which I think from the past history might run into it I immediately go for Woodbridge. I have no deaths and no protracted cases. I have placed my genuine cases at fifteen. I have no doubt the number would run much higher, but as I said before, all cases of a suspicious character are at once put on that treatment. I have seen much benefit from your plan in cases of septicemia and even in fermentative dyspepsia.

BYRON I. PRESTON, M.D., Rochester, N. Y., May, 1897:—I regret that my first cases were not properly recorded but they were apparently aborted—five of them—inside of ten days

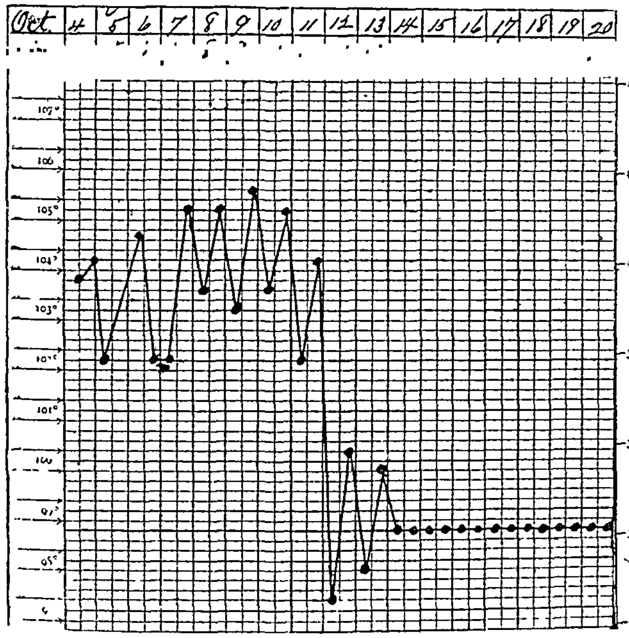
They all had nose bleed, ileac tenderness, tympanites, diarrhea and the usual temperature of typhoid fever at first.

George M. Atwood, M.D., Haverhill, Mass. :—I never saw patients with typhoid have so few unpleasant symptoms as these had after once getting down to business with the bowel.

William A. Jarnagin, M.D., Atlanta, Ga., May, 1897 :—I am perfectly satisfied with the rationale of the Woodbridge plan. Unless my experience is very different from what it has been heretofore, I will adhere to the treatment in the future. I believe this treatment is the best—it certainly appeals to common sense.

Joseph A. Daniel, M.D., Davenport, Iowa, May, 1897 :—Should I be unfortunate enough to contract typhoid fever I should want to be treated by your method.

Donald Macrea, M.D., Council Bluffs, Iowa, June, 1807 :—I learned the value of the Woodbridge treatment of typhoid fever soon after reading your first paper before the American Medical Association. Since then I have used it in all cases of typhoid, indeed in all cases of continued fever, both in hospital and private practice. I do not know how many cases I have used the treatment in nor have I any charts—I am not methodical enough for that—but I must have used it hundreds of times. I not only depend on the Woodbridge treatment myself, but I have spoken so strongly in its favor before medical societies, holding out such bright and sanguine hopes of recovery, that it is very generally used in these parts. I have never had a death since using the treatment. The duration of the disease does not seem to have been particularly shortened but the course is modified to such a degree that instead of wearing anxiety and constantly doubtful prognosis, my visits seem to be almost unnecessary and the case smoothly runs along. The only objectionable feature in the treatment is that the patient becomes tired of the bed and of being half sick.



Dr. W. R. Kelly, Watonga, Oklahoma. Goldie S., aged 11, female, admitted Oct. 4, 1895; diagnosis, typhoid fever. October 4, began treatment on fourth day of disease. Temperature below normal October 12, up to 100 on 12th, normal on 14th. Gave sponge baths and phenacetin to control excessive temperature.

Isaac A. McSwain, M.D., Paris, Tenn., May, 1897 :—The method suggested and urged by you has contributed greatly toward the limitation and alleviation of typhoid fever, and while I have seldom been able to use the exact formula of your prescriptions, yet your pointed arguments in favor of the antiseptic plan have been convincing and have caused great changes in the management of this dreaded disease. I have also used your No. 3 alone, and have been gratified with the results.

George W. Long, M.D., Graham, N. C., May, 1897 :—I have also tried the method in several cases of malarial fever with very satisfactory results (following up, of course, with quinin, etc.). At first I was much prejudiced and very slow to make the venture. Since my limited experience I feel emboldened to try the treatment further.

Henry G. Crump, M.D., Seddon, Ala., May, 1897 :—I have given your treatment a test in some cases of typhoid fever, and as far as my experience goes I think it will do all you claim.

W. H. Nixon, M.D., Killeen, Texas, May, 1897.—My uniform success has turned me from a "doubting Thomas" to a true believer. Let the physician stop and think and give the treatment a fair trial and, reasoning from my own experience I think he will be more than pleased with the result.

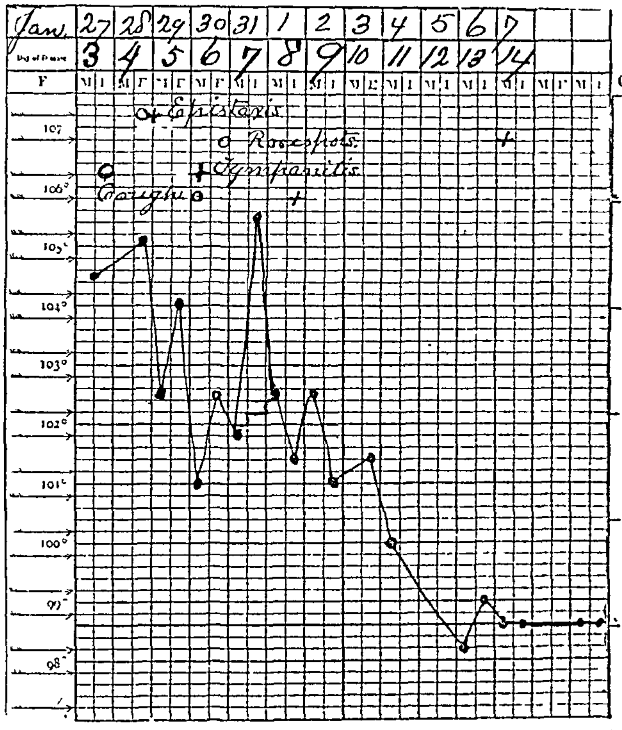
T. M. L., M.D., Virginia, May, 1897 :—I must say that I am thoroughly convinced of the efficiency of your treatment and expect to continue its use until I find some other that is better.

Matthias Bortz, M.D., Cleveland, Ohio, May, 1897 :—I have been using your system, antiseptic and eliminative, for several years, during which time I have lost no patient.

Henry W. Latham, Latham, Mo., May, 1897 :—I have been using "Woodbridge treatment" almost exclusively during the past four years; the longer and the more faithfully I apply it, the better I like it. I would be glad, and I am sure that it would be a great blessing to humanity and an honor to yourself if you would compile your ideas and experiences of the nature and treatment of typhoid fever in book form. For the principle of intestinal antisepsis is neither understood nor appreciated by one hundredth part of the profession, and after an experience of twenty-five years I admit that I groped in the dark, with no definite idea of the treatment of that terrible fever, until I got it from your writings.

Olive E. Worcester, M.D., Conant, Fla., June, 1897 :—I used the "Woodbridge treatment" of course, . . . excellent recovery.

Alfred Woodhull, M.D., Denver, Colo., May, 1897 :—One serious case came under my knowledge last year in which, partly by my suggestion, the treatment was attempted. The beneficial effects hoped for did not immediately follow and after a somewhat prolonged trial it was abandoned. The case ultimately recovered, although the illness was very grave and prolonged.



Dr. Wm. A. Morriam, Struthers, Ohio. John McE., Struthers, Ohio, aged 14; admitted January 27, 1897. Reaction of serum on Eberth bacilli positive.

R. E. Sevier, M.D., Liberty, Mo., May, 1897 :— Not one case in which I had a fair chance died.

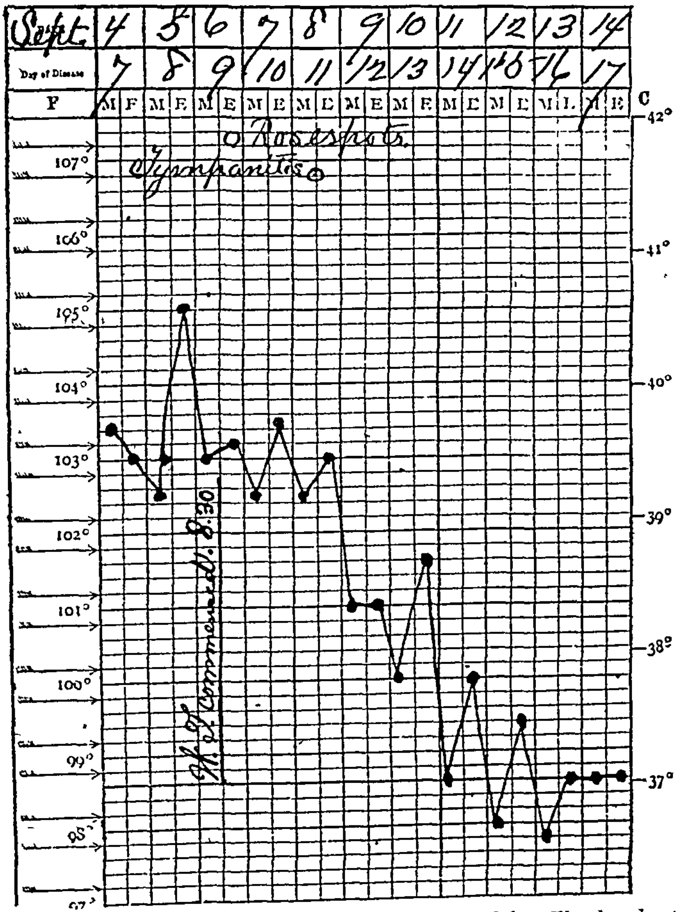
D. Y. Stem, M.D., Slidel, Texas, May 1897 :—I was gratified with the results obtained. All the literature that I had received to this date failed to outline your treatment as recommended in your recent work on typhoid fever; so, at first, I feared to give up all of the older methods and rely strictly on yours. Had I followed your instructions in full I believe I would have shortened the disease in all these cases. While your treatment is adverse to all taught in the standard works that have been examined by me, I feel now that it is the ideal treatment and that it will be a boon to suffering humanity. I wish to congratulate you on the marked success you have had in the treatment of typhoid fever and to praise the untiring energy you have manifested in trying to thwart a disease so much to be dreaded.

Richard S. Martin, M.D., Stuart, Va., May, 1897 :—I shall continue to use it in all of my cases, as I am highly pleased with the results. I am confident that it is far superior to any other known treatment.

William C. Humphries, M.D., Acworth, Ga., May, 1897:—I am a strong advocate of the "Woodbridge treatment" of typhoid fever. I am sure the mortality would be *nil* if the cases were seen in time and the treatment begun early and used persistently. I think it is intestinal antisepsis *par excellence*. I am a thorough convert to the method.

Arthur U. Williams, M.D., Hot Springs, Ark., May, 1897:—I have also used this treatment in diseases not recommended by you—malarial cases where the patient seemed to be drifting into malarial fever—general malaise, etc. Last fall my wife had all the premonitory symptoms of typhoid fever; nothing seemed to do her any good. I gave her your tablets and in a week she was on the way to recovery, and soon was all right. Many similar cases have occurred in my practice and I have been delighted with the results.

Joseph H. Green, M.D., Decatur, Ga., May, 1897:—I have been treating fevers in general by your method since last June. Several of the cases were seen for the first time in the second and third weeks of the disease, and while they ran on for two or three weeks longer, yet their symptoms were very much ameliorated and they were made comfortable and all terminated in a happy recovery.



Dr. John E. Wood, Maysville, Ohio. Patient, Walter Wood; admitted September 4, discharged September 14. Diagnosis, typhoid fever.

William P. Pierce, M.D., Hoopestown, Ill., May, 1897:—In the fall of 1895 I was called by the attending physician to see a young man, 20 years of age, dying of typhoid fever. I had been hearing for several days that his death was expected at any time and that the case was deemed hopeless. I found the patient unconscious, cyanotic, his heart beats 150, pulse at the wrist not to be detected, skin cold, and bathed in a clammy sweat, teeth loaded with sordes, low muttering delirium, restlessness and extreme jactitation, stools passing unnoticed into the bed, bowels tympanitic. The patient could not swallow. The room was filled with a sickening, cadaverous odor. We put one tablet of Woodbridge No. 1 in his mouth every fifteen minutes. He was soon able to swallow and took the tablets every fifteen minutes all night. He continued to improve—the Woodbridge method was fully carried out with almost marvelous effect, the patient slowly but regularly convalesced and in two weeks was discharged.

Ray W. Green, M.D., Worcester, Mass., June, 1897:—My cases are hardly worth reporting as, in the majority of cases, the treatment was not begun early. While I have not seen any cases aborted by your treatment, I am confident that the course of the disease was modified favorably, and the convalescence rapid.

Vilas E. Lawrence, M.D., Ottawa, Kan., June, 1897:—The disease has lost much of its dread to me. My patients begin to improve in one or two days after beginning treatment and all the symptoms die away except the fever, which gradually disappears. Most of my patients wanted more milk than I thought best to allow them. I discovered that the secret lay in giving medicine energetically and keeping the bowels well open all the time.

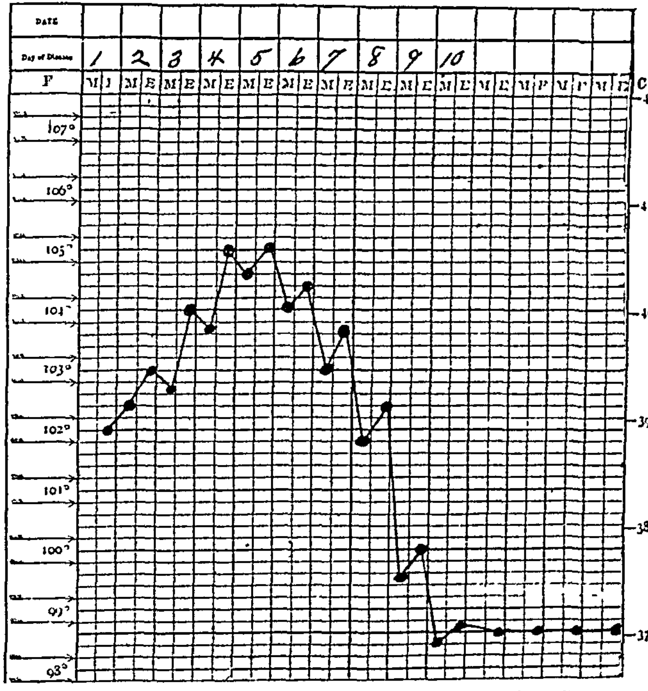
F. Marion Kent, M.D., Spring Valley, June, 1897:—I first used your method of treatment in a number of cases three years ago. My results were much better than formerly, but I did not succeed in aborting but a few of the cases. One death occurred. Since then I have been using your treatment and have had very good results—no death in three years. My results in the first cases may have been due to impurity of drugs or improper administration of the same.

Wilbert B. Clark, M.D., St. Louis, Mich., June, 1897:—One of my patients was in a family where there were two others sick with the same disease, and treated by other physicians, and both of these terminated fatally.

Granville Macgowen, M.D., Los Angeles, Cal., June, 1897:—I have treated a few cases by your method and have been pleased with the results. None of the cases died and none relapsed.

Ephraim J. McCollum, M.D., Tiffin, Ohio:—If any other doctor has had better success than I have reported, I should like to hear from him. I have been called into families where other physicians have suspected typhoid—that shows the faith of our community in the Woodbridge treatment and in those whom they know have been successful in the use of the same.

Clyde W. Crumline, M.D., Lone Pine, Pa., June, 1897:—I feel we owe a great debt of gratitude to you. My individual experience is limited, but I followed your directions faithfully. Not a dry tongue, no tympany, no "head symptoms," and in fact not a thing that I did not wish to see after the first twenty-four hours of treatment. There was no question about the correctness of diagnosis.



Dr. John F. McGarvey, Loraine, Ohio. Patient, Walter Stang, aged 18 months. Admitted March 2. Recovered. Woodbridge treatment. This was a typical case and all his friends said he would die. I said he would live.

Perley P. Comey, M.D., Clinton, Mass., May, 1897:—I have used your treatment in every case and feel perfectly satisfied with it. It is a sure thing and I advise it in all cases.

William S. Smith, M.D., St. Clair, Minn., June, 1897:—I do not hesitate to say that this treatment is by far the best yet devised for treating typhoid fever. In my hands it has yielded better results than the enthusiasts of other methods have claimed for their favorites.

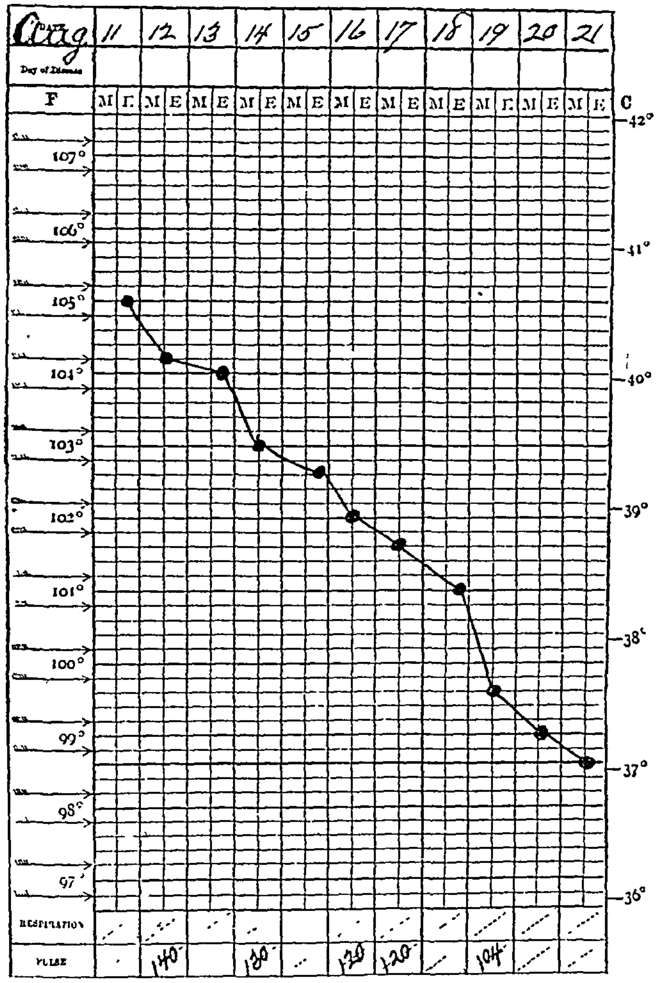
Edward L. Baker, M.D., Indianola, Iowa, May, 1897:—While I have not aborted cases, the comfort from the absence of delirium has been marked and recovery after intestinal hemorrhage has taken place—before, such cases have died in my hands.

Walter W. L. Overfield, M.D., Forreston, Ill., May, 1897:—Prior to November, 1896, I treated my typhoid patients by the older methods, but I am now convinced that the treatment advised by you is far superior to any heretofore in use.

T. W. S., M.D., Virginia, May, 1897:—Although I varied the method slightly, I consider it the only treatment to use.

Lorenzo D. Ray, M.D., Blakesburg, Iowa, May, 1897:—I remember one case, a very severe one, of a man who drank to excess. The symptoms were grave; the prognosis of consulting physicians was sure death. After consultation I began your treatment, improvement began inside of eighteen hours and his recovery was uneventful. He was married, 58 years of age a hard worker and a harder drinker. This treatment has worked exceedingly well for me in all cases especially of men who are inveterate drinkers.

Matthew K. Elmer, M.D., Bridgeton, N. J., May, 1897:—In one case it cut the disease short, but in the others, while I thought it made the cases lighter, the cerebral symptoms less severe and the patients easier in every way, and they ran a very mild course, the duration of illness was about the same as usual. However, it is a great satisfaction to have these clear minds and mild symptoms.



Dr. J. P. Matthews, Carlinville, Ill. Admitted August 11, 1895.

James A. Lifferty, M.D., Concord, N. C.:—I am well pleased with the treatment.

Milton C. Connor, M.D., Middletown, N. Y., May, 1897:—I have used the treatment, with my own modification, in every case that has come under my care for the last three years. Some cases relapsed from stopping the treatment too soon.

J. B. Taylor, M.D., Broadway, Ohio, May, 1897:—I believe the Woodbridge treatment is the best we have for typhoid fever. Hereafter I shall adhere strictly to your plan. All of my cases recovered, the average duration of illness being about seventeen days. I am *perfectly satisfied* that I was not energetic enough in the beginning. One point in particular I noticed, that while giving the treatment the tongue and teeth remained clean, the first being moist and the latter free from sordes; and there is also less distension of the bowels.

Columbus N. Udell, M.D., Blakesburg, Iowa, May, 1897:—This treatment is all right.

Stewart Robinson, M.D., Alleghany, Pa., May, 1897:—I had no relapse under this method—one case was tedious but finally made a complete recovery.

Joseph O. Yost, M.D., Youngstown, Ohio, May, 1897:—Deaths? No, indeed! I would feel guilty of an unpardonable sin if I failed to use the "Woodbridge treatment" in typhoid fever or in fact in any intestinal trouble of bacterial origin.

Warren C. Eustis, M.D., Owatonna, Minn., May, 1897:—I had one relapse but a return to your treatment prevented complications and in two weeks the patient was again convalescent.

Lowell M. Gates, Scranton, Pa., May, 1897:—I have faith in the method but think it might be improved. I do not like to give medicine every fifteen minutes, so have given two every hour. If double the strength, it would not require so many tablets. The principle of intestinal antisepsis, combined with elimination of the septic material in the intestinal tract is doubtless the correct one in the treatment of typhoid fever. It has the advantage over the Brand method in being more reasonable. To treat by the Brand method alone is as unscientific as to treat the fever of an abscess by the same method without opening and washing out with an antiseptic solution.

Joseph E. Bundy, M.D., Cissna Park, Ill., May, 1897:—We had an epidemic of rather a malignant type and I began treating typhoid in the usual way and lost two out of eight patients. Not satisfied with this I began with your antiseptic treatment and did not lose another case out of twenty. In these cases *all of the symptoms were pronounced, and in those in which* there was hemorrhage it was slight. I am satisfied that under your treatment most cases can be saved if seen in time.

Aloysius G. Blincoe, M.D., Bardstown, Ky., May, 1897:—I have never before seen eight successive cases of typhoid fever do so well.

C. W. Foster, M.D., Woodfords, Maine, May, 1897: I have used your treatment with most satisfactory results, and shall use it again if I have occasion.

George W. Hall, M.D., Saint Louis, Mo., May, 1897. We were much pleased with the effect of the remedies used. I believe that your treatment, modified to suit the requirements of individual cases, will be the treatment of the future in typhoid fever, and I feel that we owe you many thanks for directing the profession to the efficiency of "intestinal disinfection" in this disease. If we except the use of turpentine by Wood, and the use of nitrate of silver by Dr. J. K. Mitchell, to you belongs the honor of directing the attention of physicians to the intestinal canal as the place to which the main treatment should be directed.

C. Richter, M.D., Ashland, Wis.:—Most of my patients were in St. Joseph's Hospital, Ashland, Wis., and the charts are in the possession of the Sisters there. I have treated thirty cases and had two deaths. One of these had been treated by a druggist for two weeks while ambulatory drastic purgatives were given followed by salts; when the man fell into my hands he was in a *precarious condition. The outraged intestinal* mucous membranes responded by copious watery discharges, later by hemorrhages. There was an enormous tympanites and consequently and partly dependent on this, a weak heart's action. The Woodbridge treatment did not improve his condition and another hemorrhage ended the case fatally.

The second fatal case was of a nervous temperament. His wife and parents of a like disposition, proved a decided stumbling block to any rational treatment. Dr. G. W. Harrison, who treated the case, falling ill, I attended the gentleman. I remember that I predicted to Dr. Harrison a fatal termination of the case. His pulse was fast—120 to 125. His nervousness and restlessness were excessive, his general physique was anything but robust. I saw him about the second week of the disease. In his case I have the strongest reason to believe that the treatment was not properly carried out, from the mistaken kindness of wife and parents, who positively refused to awaken him to give the medicines. His life ebbed away by hemorrhages in the third week. Yet in his case, I noticed some of the symptoms—or rather the absence of the symptoms usually met with in typhoid fever under this treatment and of which in a general way I shall speak later. I consider both of these cases for obvious reasons as not properly to be classed under the head of those patients in whom I exhibited the Woodbridge treatment; however, I desire to be unbiased in the matter and consider it my duty to mention these cases and something of their history to you. Outside of these cases I have had no death while using the Woodbridge treatment in typhoid fever. My observations while treating typhoid fever patients with the Woodbridge treatment show that the disease has run a much shorter course than usual *in typhoid fever.* In several cases, fever stopped on the fifth and sixth day. Tympanites was entirely absent in all cases, after commencing. The stools, usually two in number during twenty four hours, while soft, were not diarrheic nor very offensive. There never was a diarrhea with the characteristic pea soup stools, but the

> discharges were rather of a pultaceous nature. There was entire absence of distressing nervous symptoms—no severe headaches, no jactitation, no complications, no excessive thirst. In fact I base my recommendation of this treatment more upon its beneficial influence in abating these symptoms, than in particularly aborting or cutting short the attack, although it certainly has done so in several of my cases. My patients appear to me never to be very sick while under this treatment. The general clinical aspect of the disease was entirely changed and I say this after having seen and treated hundreds of cases of typhoid fever.

These are a few brief quotations from the reports of 193 physicians who have treated (since their previous report, or since they commenced the use of the treatment) 2,078 cases, with forty-five deaths. All of these reports have been received since I presented my paper to the Ohio State Medical Society on May 21, 1897, which gave the statistics of 5,449 cases and 105 deaths, all that had been reported to that date.

The statistics now show 7,827 cases treated with 150 deaths, a death rate of 1.91 per cent. This includes every death known to have occurred under the treatment, or any modification of it. Several deaths in which the treatment was known not to have been properly applied, a large number in which the treatment was not commenced until after the patient was moribund or practically so, and eleven in which the patient was so near the end when the treatment was commenced that death actually occurred within from eighteen to forty-eight hours, and a few cases in which the death was not due to typhoid fever or its sequelæ, are included. In only seven of the fatal cases do the reports show that proper treatment was instituted on or before the eighth day of the disease.

The average duration of illness in the 4,935 of the cases which recovered and in which it was given, was 12.7 days. Of the cases that recovered, 101 had intestinal hemorrhage. Ninety-five relapses are reported. Forty-seven were pregnant women, of whom two miscarried and died, six miscarried and recovered, and thirty-nine carried their children to full term, two giving birth to twins. In every instance in which the condition of the child is mentioned it is described as "fine," or "healthy," or "fine and healthy." Forty of the cases were complicated with pneumonia and recovered.

In 85 of the fatal cases the cause of death is given, 12 being due to intestinal hemorrhage, 14 to perforation, 10 to pneumonia. Six of the deaths are said to have been due to meningitis, 3 to consumption, 3 to Bright's disease, 2 to intussusception, etc. The stage of the disease at which the treatment was instituted is given in 69 of the fatal cases, in 10 of which it was from the first to the eighth day, in 10 from the eighth to the tenth day, in 14 from the tenth to the fourteenth day, in 16 from the fourteenth to the sixteenth day, and in 19 from the sixteenth day to the end of the third week. In 66 of the cases the stage of the disease at which the treatment was commenced is not stated.

These are the statistics and these brief quotations, together with the more than one hundred pages of closely typewritten excerpts from earlier reports presented to the Ohio State Medical Society, on May 21, constitute the verdict of the only jurors who are competent to render judgment, viz.: those who can speak from bedside experience. Among all these hundreds of reports, there appear but twelve adverse critics, not one of whom could possibly have been in possession of any accurate knowledge of the subject, not one of whom had written to me for advice, nor called me in consultation, nor read the one published article in which I have given detailed directions for the management of typhoid fever. At least seven of the twelve, by their own admission, and one other certainly, did not use the treatment as advised, and the remaining five spoke from an experience limited to the treatment of fifteen cases, an average of three cases to each observer. This is an experience altogether too insignificant to justify an adverse criticism.

What are the salient features of this mass of reports of physicians who have broken away from the ideas of the past? These reports show that those who followed the directions given in my book, "Typhoid Fever and its Abortive Treatment," most closely, had the best results and have become the most enthusiastic advocates of the method and, vice versa, those who diverged most widely from the prescribed course met with failures. They show that many dangerous modifications have been made and that some of the deaths are due to these alterations. They show that rapid recoveries have followed its use when first applied at all the different stages of the disease, and even after all hope had been abandoned by the attending physicians who had used other methods, and in several instances after the supervention of alarming intestinal hemorrhage, they show rapid recoveries during the most careless and injudicious use of the most subversive counterfeits of the original prescriptions. They show the administration of such infinitesimally small doses as would make the most orthodox homeopath blush and of doses the size of which would make the rashest heroic of the past tremble.

Despite these encumbrances, the method of treatment has passed through the ordeal of its first years of trial by both its friends and its enemies, who have treated 7,827 cases with 150 deaths, or a death-rate of less than 2 per cent. and a duration of illness of a trifle over twelve days. Under its benign influence the severity of the disease is greatly ameliorated, the symptoms minified, all grave complications averted and dangerous sequelæ prevented. The tongue is quickly rendered moist, tympanites promptly relieved, excrements lose their offensive odor, delirium is rare and the "typhoid state" unknown. The appetite soon returns and the patient expresses a desire to get up and eat solid food, which he may do if he has been properly treated from a sufficiently early stage so that ulceration of Peyer's glands has been prevented. Tedious convalescence is avoided, the patient generally passing rapidly from the fastigium of the disease to vigorous and robust health. These are results which have never before been obtained in hospital or private practice, in so large a number of cases, by so many physicians. They are results which were never before deemed possible. They have been obtained in most instances, without the use of the cold bath, medicinal antipyretics, or alcoholic stimulants, all of which are generally unnecessary. They prove by incontrovertible evidence that typhoid fever can be aborted. They teach that it is amenable to curative treatment in all of its stages and they go far toward proving that death or protracted illness are wholly unnecessary consequences of the disease

In conclusion I wish to say that I am deeply grateful to the physicians who have so courteously and courageously responded to my letters of inquiry and in so doing have made it possible for me to submit this report.

637 Prospect Street.

TRICHINOSIS IN THE UNITED STATES; WITH THE REPORT OF A CASE.

Read in the Section on Practice of Medicine, at the Forty-eighth Annual Meeting of the American Medical Association held at Philadelphia, June 1-4, 1897.

BY FREDERICK A. PACKARD, M.D.
PHILADELPHIA.

Feb. 5, 1897, an Italian was admitted to my ward at the Philadelphia Hospital, complaining greatly of pains in the thighs and legs. Owing partly to his natural mental obtuseness, partly to his nationality, the history that could be obtained even with the aid of an interpreter, was by no means satisfactory. On this account many points in his history are vague, while some of the facts in his case could not be determined.

He gave his age as 28 years, his occupation that of a farm hand. He could give us but little information in regard to the locality in which he had last worked, but said that it was in New Jersey. After three months of enforced idleness (from lack of work) he started to work on a farm on February 1. The work being too laborious for him he left the farm, although he seems not to have felt ill in any way. On the third of the month (two days before admission) he had a decided chill, with some vomiting but no diarrhea. On the day of admission the face had begun to swell. As to the dates recorded there may be some doubt, although repeated questioning only seemed to confirm the statements made above.

On examination it was found that he was a rather strongly built man. There was quite marked edema of the eyelids and the surrounding skin, especially above the brows. The swelling was quite sharply marginated above and over the malar bone, the skin being quite red and rather shiny. The pupils were equal and natural. The pulse was of good force, full volume and rapid. The tongue was slightly coated and rather dry. Examination of the heart and lungs showed nothing abnormal. The abdomen was rather scaphoid, showed no tender area or gurgling and there was no eruption. The areas of hepatic and splenic dulness were normal.

The joints were free from swelling, redness or heat. There was no visible change in the painful parts but the least pressure upon the legs or thighs at once caused complaint of pain. This tenderness was diffuse, in that it did not correspond to nerve trunks, blood vessels or bone, but was decidedly more marked toward the ends than over the belly of the muscular masses. The temperature on admission was 101.4 degrees, the pulse 94, respirations 20.

Sodium salicylate, gr. x, every three hours, and also a sponge bath if the temperature reached 103 degrees was prescribed. The patient passed a sleepless night, and on the next day complained rather more bitterly of muscular pain in the thighs and legs and also in the arms. Examination of the urine showed that it was yellow in color, of acid reaction, specific gravity 1025 and contained no albumin, but in the sediment there were found a few granular casts and leucocytes. He complained much of thirst and dryness of the mouth.

A daily record of the events of the case would be rather devoid of interest and it will suffice if the main facts of the clinical course are noted. The pain in the muscles of the thighs and calves continued without intermission until March 2, almost a month from the time of onset, although it is questionable whether they were very severe during the latter part of this time, inasmuch as they suddenly departed on that date, after a small incision of the calf. Insomnia was a marked feature for the first eleven days of his stay at the hospital. There was no vomiting after admission. The bowels moved three times on the day after admission, twice on the 9th and five times on the 10th of the month; but were simply brown, watery movements without distinctive character.

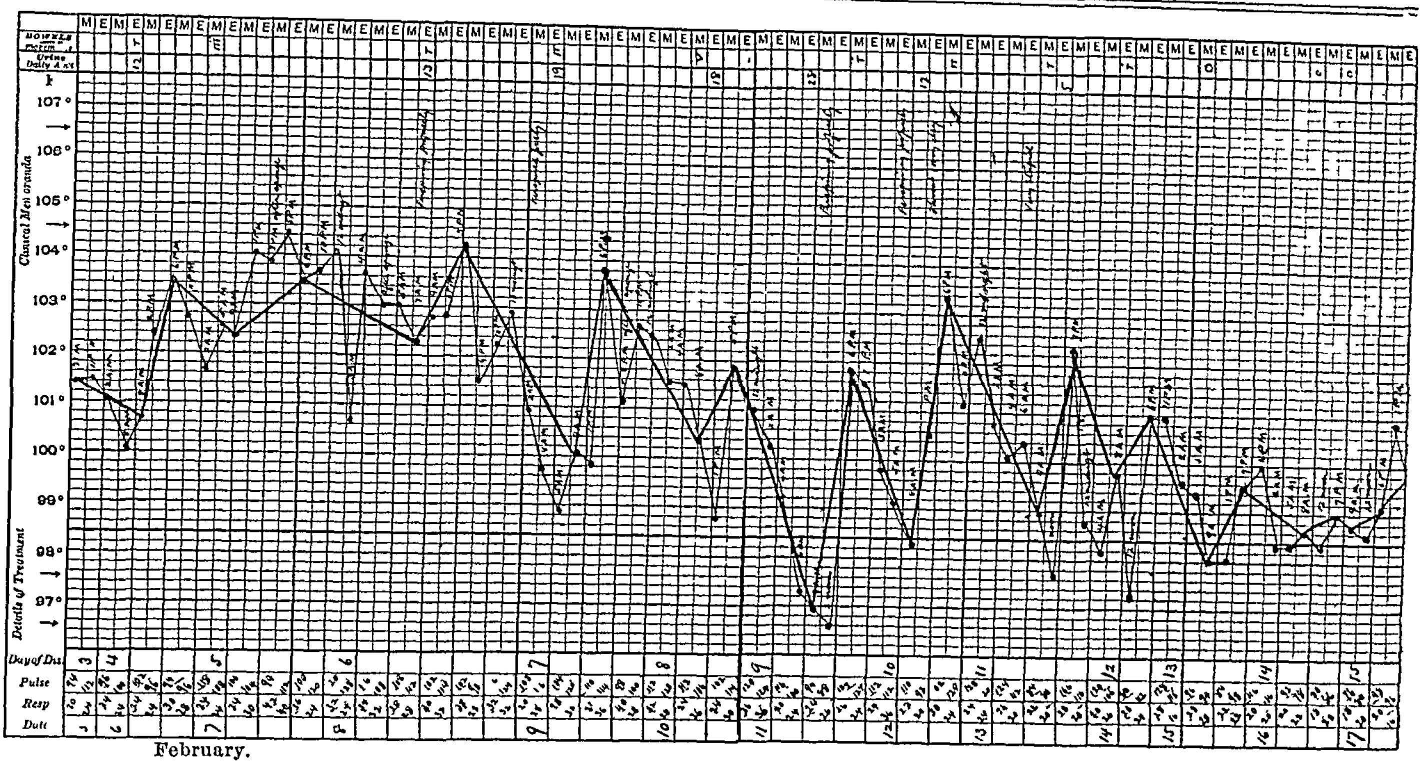
The edema of the face subsided after four or five days and the skin at once presented its normal appearance. There was no swelling, ecchymosis or redness of the conjunctiva at any time.

On February 9, the sixth day of his illness, the fourth day after admission, some small red spots were found on the abdomen, which were caused to disappear by pressure and were called "suspicious." These persisted but a day or two and were not succeeded by others. There was slight cough on and for a few days after February 16, with scanty, glairy white expectoration. This was examined on the day of appearance and a few tubercle bacilli were found. As the diagnosis of trichinosis had been made with quite positive certainty before that date and as there were no physical signs of lung involvement, subsequent careful examinations were made, always without result. and it was concluded that the presence of bacilli in the first examination must have been due to accidental contamination.

The urine was scanty, at times only measuring from twelve to nineteen ounces in twenty-four hours; the specific gravity was invariably high, ranging from 1024 to 1027. No albumin was ever found, but in two examinations there were found granular casts; on one occasion on ordinary sedimentation without the aid of the centrifuge. No estimations of urea, uric acid, etc., were made. Profuse sweating was present on four days (from the tenth to the fourteenth day of his illness).

The temperature, as will be seen by the accompanying chart, pursued a remitting course from the time of admission until March 9. For the first two days it progressively increased until it reached 101.4 degrees, then suddenly fell to 100.6 degrees, only to soon rise to over 103 degrees. On the ninth of the month (the sixth of the disease) he had but little fever for the greater part of the day, then the temperature quickly ascended to 103.8 degrees, to fall irregularly almost to the normal point on the next afternoon. On February 11 it suddenly descended to 96.6 degrees with no apparent cause other than profuse sweating, and from that date became extremely irregular until February 16. From that time onward it pursued an erratic course of slight elevation above the normal until it finally settled to the normal on March 9.

The pulse was accelerated during the whole time of fever but was not out of proportion to the elevation of temperature. At the latter part of the febrile period it became rather soft and compressible. The respirations were abnormally numerous from the day of his admission until several days after his temperature had remained at the normal point. As will be pointed out later, this was one of the most potent factors in arriving at the diagnosis. On February 23 the feet and legs were found to be very edematous, white in color and pitting deeply on pressure. This persisted until his discharge from the hospital on March 25.



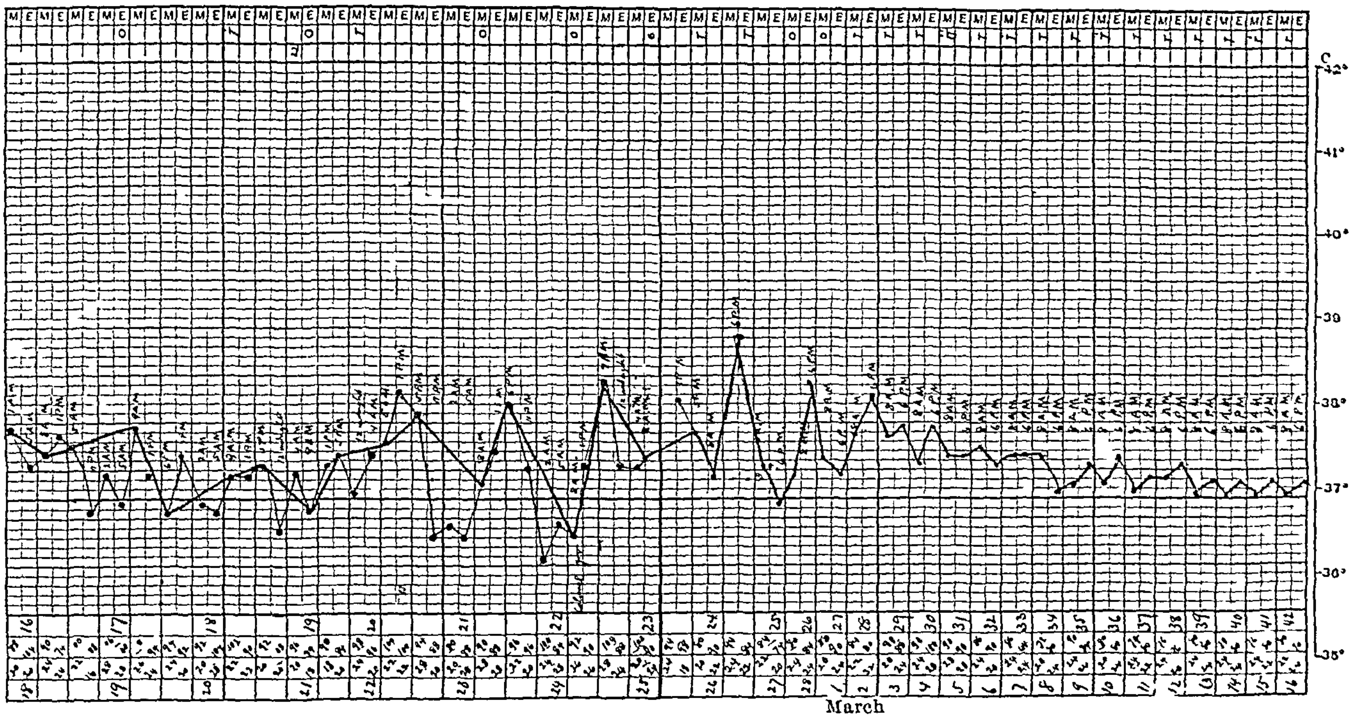
The blood was examined March 10. The result showing 4,230,000 red cells per c.mm., hemoglobin 74 per cent., 8,000 leucocytes per c.mm. After reading T. R. Brown's "Studies on Trichinosis," in the *Johns Hopkins Hospital Bulletin* for April, 1897, I much regretted that repeated examinations with differential estimation of the leucocytes were not made. The estimation of the relative proportion of eosinophiles would have been especially interesting in view of Brown's finding a percentage of these corpuscles as high as 68.2 per cent., with corresponding decrease in the polymorphonuclear neutrophiles to 6.6 per cent. Brown's discovery of great leucocytosis (30,000 per c.mm.) was certainly not present in our solitary examination on the thirty-fifth day of the disease.[1]

Dr. C. A. Oliver kindly made an examination of the ocular conditions and furnished me with the following report: "Vision and accommodative power normal. Pupils 3.5 mm.; irides equally and freely movable to the light, convergence and accommodation, marked hyperphoria for near and far, eye ground normal with the exception of a fine striated hemorrhage partially overlying the inferior temporal vein just beyond its primary bifurcation in the left eye. Field of vision normal. *Summary:* No gross ocular changes except a slight disturbance in extra-ocular muscle equilibrium in the vertical meridian, and a fine isolated venous extravasation in the superficial layers of the left retina." The voice was at no time husky or altered beyond the changes produced by the dryness of the mouth. Laryngoscopic examination was negative. Hearing was at no time impaired.

On February 25 I lectured on this case in the clinic, giving the following reasons for my diagnosis: There were but six possible diagnoses: typhoid fever, rheumatism, influenza, non-discoverable tuberculosis, myositis from cause other than the trichina spiralis and trichinosis. Typhoid fever could be excluded by the atypical temperature curve, by the facial expression, the appearance of the tongue, the absence of tympanites, the lack of splenic enlargement, the character of the stools and the absence of the ordinary prodromal symptoms of that disease. The few "suspicious" spots on the abdomen were not atypical of typhoid and were not succeeded by other skin lesions. No form of rheumatism would give us such symptoms as we had in this case, except the so-called "muscular rheumatism," which is usually accompanied by but slight elevation of temperature, is seldom distributed in the manner here present, is seldom accompanied by pain of such acute character and would in no way account for any of the symptoms here present except the muscular pains. Influenza could with rather more difficulty be excluded, but was ruled out by the long continuance of the pain and temperature and by the extreme muscular tenderness present, while the occurrence of many of the symptoms could hardly be accounted for by even this protean malady. Non-discoverable tuberculosis should only be diagnosticated after careful exclusion of every other possible cause for the symptoms, and in this case there was no good reason for suspecting its presence, while it would only account for the temperature elevation and would not explain the peculiar pains. No cause for a non-trichinous myositis could be found. In favor of trichinosis were the muscular pain and tenderness, chiefly near the tendinous insertions of the muscles, the history of vomiting at the outset, the atypical and irregular temperature curve, the insomnia, the thirst, the sweating, the rapidity of respiration, but above all by the early swelling of the upper face and the late edema of the feet. Two points militated against the diagnosis—the absence of early diarrhea, the vague history of the eating of raw pork and the absence of other known cases of infection. The absence of diarrhea showed but little, inasmuch as it is by no means constantly present in trichinosis. Careful inquiry showed the occasional eating of bologna sausage as the only probable source of infection, while the fact that the patient immediately left the place where he probably contracted the disease and his ignorance as to his fellow laborers rendered futile any attempt to discover the existence of other

---

[1] Cabot (A Guide to the Clinical Examination of the Blood, 1897, p. 102) says that a case has lately been observed in Dr. Osler's clinic at Johns Hopkins Hospital with a leucocytosis of 25,000, and 61 per cent. of eosinophiles. It is possibly the case reported by Brown and referred to above.



cases. The two points that made me feel most certain of my diagnosis were the occurrence of frontal edema and the otherwise unaccountable rapidity of respiration, the latter being readily explained by the predilection of trichinæ for the diaphragm.

On March 2 the patient consented to the removal of a piece of muscle from the left gastrocnemius. A small piece was excised and showed a very large number of living, non-encapsulated embryonal trichinæ scattered among the muscle fibers. The operation greatly relieved his pain, so that there was no difficulty in gaining his consent to a second exploration in the gastrocnemius of the right leg on March 17. This specimen showed a great number of embryos with beginning capsule formation.

Some of this muscle fiber was fed to two white rats for experimental purposes, and it was my desire to present to this meeting some results of feeding experiments, but unfortunately I have not been enabled to complete my study of this portion of the subject in time to give my conclusions at present. Through the kindness of Dr. D. E. Salmon of the Bureau of Animal Industry I obtained a large supply of trichinous meat, which I have fed to white rats and guinea pigs in order to determine some of the still undecided questions in regard to the path of migration of the embryos and to the finer changes in the infected muscle fibers, but the investigation has required more time than I have been able to devote to it and I shall have to report my results in a later communication

This is the fourth case in which I have made the diagnosis of trichinosis during life, but the first in which I have been able to persuade the patient to allow me to make the one crucial test in sporadic cases—the excision and examination of a piece of muscle. That many cases of infection by trichinosis must occur annually in this country can, I think, not be doubted. I regret that it was not in my power to further follow up the source of infection of my patient. When last seen my patient was steadily gaining flesh and had returned to work.

In the Twentieth Annual Report of the State Board of Health of Massachusetts, published in 1889, there is an interesting paper by Prof. E. L. Mark, of Harvard University, upon "Trichina in Swine." Between the years 1883 and 1888 he examined 3,061 hogs raised near Boston. Of these 394 or 12.86 per cent.were trichinous. Of 3,298 hogs raised in Massachusetts, 436 or 13.22 per cent. showed trichinæ on examination. Of the 234 examined hogs slaughtered for State institutions, 42 or 17.95 per cent. were trichinous. The pork intended for export or interstate trade (see 8th and 9th Annual Report of the Bureau of Animal Industry, 1891) is inspected, and if found free from trichina by the inspectors of the Department of Agriculture, is labeled as inspected and passed. For the year ending June 30, 1882, 1,267,329 hogs were examined. Of these, 25,899 were trichinous, 2.013 per cent. As the trade in pork within the States does not receive official inspection it may be that the figures given by Prof. Mark for Massachusetts are not very much, if at all, above the average of other States. If so, there must be frequent infections. Reports of individual cases, such as is the present contribution, are of but little value as compared with the accounts of groups of cases, yet I can not think that the disease is frequently diagnosticated when so little mention of it is found in the journals. Possibly the observers of the disease have not thought the subject sufficiently interesting to make it worth their while to publish their isolated cases. I hope that their opinion is not correct.

In order to obtain some idea of the prevalence of trichinosis in the United States and Canada I have tabulated the cases reported in the various journals, in so far as they are accessible to me. A tabulated list of these I have appended to this paper. The results may be summarized as follows:

Between the years 1861 and the present time there have been reported in the United States and Canada 357 cases of trichinosis. Of these, 243 recovered, 80 died, while in 17 the result is not stated. The mortality, therefore, of the 323 cases where the result is definitely stated, was 24.76+ per cent. The total above given is probably far to small, inasmuch as a large number of the reporters state that many cases

ANALYSIS OF CASES OF TRICHINOSIS OCCURRING IN THE UNITED STATES AND CANADA.

No.	Year.	Reporter.	State.	Place of Publication.	Total.	Recovered.	Died.	Remarks.
1	1864	Krombein	New York	Buffalo Med. and Surg. Jour., June, 1864, p. 430	7	5	2	The five marked as recoveries were still dangerously ill at time of report.
2	1866	T. S. Bardwell	....	Med. and Surg. Reporter, June 14, 1866				The same as those of (3) H. Ristine. Inserted owing to slight precedence of date of publication.
3	..	H. Ristine	Iowa	N. Y. Med. Record, July 16, 1866	9	4	5	Same cases reported by E. M. Smith, Chicago Med. Jour., Aug, 1866; Jos. H. Wilson. Med. Rep., St. Louis, 1866, and T. S. Bardwell (2).

occurred where medical aid was not sought. By the second table it will be seen that cases of the disease have occurred in seventeen States, in the District of Columbia and in Canada. The State from which the the largest number of cases has been reported is New York, which also heads the list in regard to the number of reports. On the other hand the largest definitely estimated epidemic occurred in Massachusetts. The greatest number of cases reported in one year occurred in 1892, when there is seen to have been more than fifty-one cases. The reason for this can not be given and there is no evidence of any growing frequency of the disease before or after that year. There occurred in that year three outbreaks of considerable size, two in Massachusetts (15 and 21+) and one in Mississippi (19).

In conclusion, I report this isolated case in order to again draw attention to a disease that I believe may be of greater present importance than is usually thought, and also to draw particular attention to a symptom that did much to guide me to a correct diagnosis—the great rapidity of respiration without other evident cause. I mention this symptom especially for the reason that, while many state that symptom was present in their cases, I do not believe that sufficient importance has been attached to rapid respiration as a prominent symptom of this affection. Finally I would urge the importance of certainly excluding trichinosis before making the much abused diagnosis of muscular rheumatism.

A REPORT OF TWO CASES OF MYXEDEMA WITH REMARKS ON AN ANOMALOUS TYPE.

Read in the Section on Practice of Medicine, at the Forty-eighth Annual Meeting of the American Medical Association held at Philadelphia, Pa., June 1-4, 1897.

BY J. M. ANDERS, M.D., LL.D.
PHILADELPHIA, PA.

Myxedema is a general disorder of metabolism, dependent upon diminished or lost thyroid function. Among various morbid processes affecting the gland and which have been observed to give rise to myxedema are the following: atrophy, atrophy associated with calcareous degeneration, atrophy with enlargement of the pituitary body, actinomycosis, syphilitic degeneration of the organ, and the presence of neoplasms. It is to be recollected, however, that disease of the thyroid is not followed by cachexia strumipriva, provided even a small portion of the gland remains functional. The truth of this dictum was shown by the postmortem findings in the case contributed by Sieveking,[1] in which sarcoma had invaded the thyroid. This fact is also fully confirmed by the results of experimental extirpation of the thyroid in animals: total removal of the gland is regularly followed by myxedema (except functional accessory thyroids be present), while if even one-tenth of it is allowed to remain, the animal escapes the disease.

Of intense interest are recorded cases in which myxedema is either associated with or occurs in persons who have previously suffered from exophthalmic goiter. Baldwin[2] reports four cases belonging to this category. The first occured in a boy of ten, four years after Graves' disease; the second affected a girl of fourteen, two years after the exophthalmic goiter was cured; the third, a girl of fifteen first showed signs of myxedema five years after improvement from Grave's disease; and the fourth, a woman of forty-four, four years later.[3] It is an almost universally accepted belief that exophthalmic goiter is dependent upon excessive thyroid secretion the direct antithesis of myxedema. Like cachexia strumipriva, exophthalmic goiter is held by the weight of authority to be caused primarily by thyroid changes that bring about "thyroidation." Accepting this view it is quite conceivable that morbid processes first causing over-stimulation of the gland, may, in their future progress, lead to abnormally feeble or an entire absence of glandular secretion, and thus the former condition may predispose to the latter. The tendency to myxedema may be observed in several members of the same family, but I believe this to be rare.

The complex symptom-group of typical cases of myxedema is at present writing well known, and the literature bearing on this aspect of the subject is so extensive as to be much beyond the compass of this article. The following cases are reported: 1. For the reason that one of them manifested certain features of unusual significance. 2. To confirm the well-deserved professional favor gained by thyroid extract in the therapy of this disease. 3. To discuss a few of the main questions which have been raised in connection with the subject of treatment; and lastly, to direct attention to an anomalous or a rudimentary type that yields easily to sheep's thyroid.

Case 1.—M. R., age 50, female, fell ill about fifteen years ago, showing symptoms that were of slow and gradual development, becoming eventually typical of this affection. When I first saw the patient, the neck and supraclavicular regions were observed to be bloated; also the face, giving rise to a peculiar physiognomy. The features were bulky and expressionless, the face broadened, and the lineaments were practically obliterated; the lips were greatly thickened and the tongue markedly swollen. The general bulk of the body was obviously increased. The pressing finger showed an absence of pitting, even over the face, where stiff edema was most marked. A circumscribed red patch was noticeable on the cheek. The skin, particularly the backs of the hands, was dry, rough, somewhat scaly and inelastic; the nails were quite brittle, the hair was coarse and constantly shed.

The mental symptoms were not striking, except that thought and speech were slow, and the tone of the voice, was characteristically leathery. Hallucinations and impairment of memory were not observed. Occipital headaches and neuralgic pains were frequently complained of, as was also muscular weakness. The temperature was slightly subnormal (98 degrees), but cold hands and feet were not experienced.

[3] Gould's Year-book of Medicine and Surgery, [illegible].

There was slight though decisive albuminuria, and this symptom I learned had been present for four or five years at least, with hyaline and granular tube-casts at intervals.

On account of the presence of persistent albuminuria, her former physicians, two in number, had diagnosticated chronic nephritis. Temporary albuminuria with casts, is frequently met with in this disease, but the persistent characteristic features of chronic Bright's are not seen. After treatment with extract of thyroid for six weeks, the urine presented no abnormalities; neither has albumin or casts reappeared since then (as shown by repeated testing). Believing herself to be a sufferer from renal affection, and being possessed of superior intelligence, I was unable for a long time to induce the patient to make a trial of thyroid extract.

The interesting features were limited to the urinary phenomena. The relation of mere albuminuria or actual nephritis to myxedema is not definitely known. On the other had, it should be pointed out that the symptoms of Bright's have been observed to appear after the accomplishment of a cure by thyroid feeding, in cases in which no urinary phenomena had been present during the course of myxedema.

Case 2.—Mrs. Rebecca Coates, aged 50, a patient under the care of Dr. A. E. Roussel at the dispensary service of the Howard Hospital.[4] Mother died of phthisis, father killed in an accident. Patient has been in the best of health until three years ago, when menstruation ceased. Has had several attacks of rheumatism, and recently, the body in general has been getting more and more bulky. The face at present is puffy and edematous-looking, but does not pit on pressure. The skin is rough and dry and the lips blue. The hair is dry and falling out. The nails are clubbed and brittle. Her expression is heavy and stupid; the speech is slow and hesitating and the voice rough. The memory is impaired and she frequently suffers from headaches. Mental aberrations occur frequently, she talks incoherently and believes she sees objects. There is a certain stiffness and clumsiness in the gait. The respiration is slow. Her temperature is 98 degrees and she complains of feeling cold. She is easily fatigued, complains of a *bitter taste in* the mouth, has a poor appetite, and her bowels are irregular. The urine is normal (specific gravity 1020, *no* sugar, albumin nor casts present).

Treatment was commenced on March 20; the patient was asked to lead a quiet life and was put on the extract of thyroid, grs. iii, three times a day. On March 23 the patient returned and stated that since taking the remedy, she suffered greatly from pain in the stomach and bowels, and at night from aggravated nervous symptoms, such as mental wandering and the apparent sight of different objects. The dose of the remedy was then reduced to 1 gr., three times a day, and on March 27 the patient came back complaining that the medicine still disagreed with her and produced profuse sweats.

On April 1, the dessicated thyroid powder was ordered, grs. 3, three times a day. On April 6, the dose, which had been well-borne in the meanwhile, was increased to grs. 5, thrice daily. On April 10, she presented herself again and reported that she had been troubled with copious sweats, and had noticed that her weight (found to be 168 pounds at this time), was decreasing. On April 13, the thyroid gland powder was increased to 7 grs., three times a day, and on April 17, she complained of severe pains pains in the limb particularly the legs, and a burning sensation in the stomach. After the use of small doses of hydrochloric acid, internally and of chloroform liniment, locally for the *leg* pains, relief came. The patient did not return for eleven days (May 1), or about six weeks from the date of the commencement of the treatment. At this time the bloating of the hands and face had largely disappeared; the voice was less harsh and leathery in tone, and her weight 160 pounds. On April 18 she presented herself again apparently in excellent health, and expressing herself as being free from gastric or other symptoms. Her weight was now 143 pounds, a loss of 25 pounds while under treatment with thyroid gland powder.

As the result of wide experience, to which a mite has been contributed by many *different clinicians*, the specific virtues of sheep's thyroid in the treatment of pure myxedema have been conclusively established. It is also the unanimous opinion of writers, that certain precautions must be taken during the administration of this remedy. The commencing dose must be small, since many individuals are remarkably susceptible to the action of this agent. Thus in case No. 1, not more than one grain daily of the thyroid gland powder could be tolerated at first. The dose was very gradually increased, until at the end of the fourth week, five grains daily were well borne, and the myxedematous condition rapidly disappeared under this small dose. This patient took three doses of 3 grains each on the same day, and after the last, symptoms of hyperthyroidation developed. There were *intense* headache and syncope, *with a feeling* of powerlessness in the legs. Rest in bed for a short period, and the use of cardiac tonics soon caused these symptoms to disappear. Subsequently, I combined with each dose of thyroid extract, gr. 1-36 of strychnin sulph., and after that no toxic effects were observed. There can be no question but that the evidences of cardiac failure constitute a really serious defect, and perhaps, the only one in the thyroid treatment. Murray[5], who first used thyroid extract in the treatment of myxedema, lost two of his early cases from cardiac failure, brought on by over-exertion. This observer strongly recommends rest in bed for a time after treatment has been instituted, with a view to avoiding cardiac and arterial strain. This may be necessary in long-standing cases, *and in those in which "cardiac or vascular degeneration"* are present. Ordinarily, the administration of *strychnin* will be found to avert any dangerous degree of cardiac failure, and this should not be omitted until a cure is effected. Only the gentlest exercise is permissible during the same period.

Case No. 2 manifested toxic symptoms (gastro-intestinal pains, profound sweats, etc.,) from the administration of small doses (gr. 1, t. i. d.) of the glycerin extract of thyroid. It is worthy of repetition that the desiccated thyroid gland could be taken by this patient in doses three times as large as the glycerin extract, and *without* unpleasant or toxic effects.

Not all of the symptoms that follow the administration of thyroid are due to over-dosing. As pointed out by Murray, an increase in the pulse-rate amounting to ten or twenty beats per minute simply indicates that the dose is quite large enough. In case No. 1, a most intense itching over different parts of the skin-surface occurred at intervals, and caused intolerable distress; a diminution in the size of the dose did not seem to influence the course of this symptom. The phenomena to be watched for and to be regarded as adequate reasons for stopping the remedy, are numerous, and are not sufficiently emphasized in our text-books. They are tachycardia (over 100 beats per minute), elevation of the temperature (amounting to one or more degrees), syncope, vertigo, suffusion of the face, profound prostration, intense headache, profuse sweats and gastro-intestinal disturbance. Granting that exophthalmic goiter is attributable to hyperthyroidation, if during the administration of thyroid glands symptoms of this disease, such as slight tachycardia, fine tremor, exophthalmos, heat and sweat, insomnia, restlessness, polyuria, glycosuria, or albuminuria and the like appear, the dose should be reduced, but the remedy need not be discontinued. It is well understood, that after total disappearance of the myxedematous infiltration, the treatment may have to be continued off and on, if not continually; this is due to the fact that the thyroid is no longer functional, being as a rule atrophied.

---

[4] The notes of this case have been kindly prepared by Dr. Mishkin.

[5] British Medical Journal, April 13, 1891.

Examples of what may be regarded as an anomalous type, that do not seem to progress to the fully developed disease with its characteristic clinical picture, are, I am certain, not infrequent. They are not to be regarded as instances of cretinism, since they develop after the age of 15 years, and few of the characteristic symptoms of myxedema are present. The face is rather flat, the skin somewhat swollen, dry, firm and inelastic. The features also lack mobility, but are not so coarse or bulky as in true myxedema. The physiognomy is dull, uninteresting and phlegmatic. There is a slight increase in the general bulk of the body, but the lips, nose and tongue are chiefly implicated. The lower jaw may be prognathic. The gait is somewhat uncertain, owing to trivial disturbance of coördination. There is some alteration of the voice with a tendency to occasional nasal explosions during speech. Thought is somewhat slow and the memory lags. Other mental phenomena are irritability of temper and an unnatural degree of suspiciousness though not so pronounced as in typical cases. Such patients are often apathetic or even melancholic and if constipation or gastric disturbance be present, a supposed chronic dyspepsia is liable to be mistaken for this complaint. There is also danger of confounding these cases with neurasthenia. Even in the presence of the above symptom-group it is not possible to make an absolete diagnosis, but the therapeutic test (improvement under thyroid feeding), if properly made, clears the doubt with reasonable certainty. I have recently observed the disappearance of a grouping of symptoms such as I have described in two cases as the result of the administration of sheep's thyroid. One of these patients had been treated for nervous dyspepsia and constipation for a long period of time.

THE TREATMENT OF EXOPHTHALMIC GOITER AND OTHER VASOMOTOR ATAXIAS WITH PREPARATIONS OF THE THYMUS GLAND AND OF THE ADRENALS.

Read in the Section on Practice of Medicine, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY SOLOMON SOLIS-COHEN, M.D.
PHILADELPHIA, PA.

I desire to make a brief report of a number of cases of exophthalmic goiter, and of conditions more or less closely resembling exophthalmic goiter, treated by means of extract of the thymus gland and of the suprarenal capsule. It is not my purpose in this paper to discuss at length the vexed questions of the etiology and pathology of Graves' disease, and of those conditions to which I have in a previous paper given the name of vasomotor ataxia. Nevertheless, some slight allusion to these subjects is necessary to make myself fully understood. I hold that there are almost innumerable varieties of disturbances of the cardio-vascular balance, ranging from the merest departure from the normal, to the most pronounced case of Graves' disease on the one hand, and of Raynaud's disease upon the other. The principal clinical phenomena of these conditions are disturbances of the heart's action, and central or peripheral phenomena indicative of abnormal contraction or dilatation of the vessels. The essential element is incoördination or ataxia of the circulatory mechanism, and among more or less prominent secondary symptoms are murmurs in the heart and vessels; blood losses which may range from severe pulmonary, uterine or renal hemorrhages, to slight epitaxis, hematemesis or hemoptysis, or perhaps merely petechiæ upon the skin, or the presence of blood cells revealed only to microscopic search in the urine; headache or vertigo; syncope with flushed or with pale face; local heat and redness of ears or face, usually unilateral; numbness and tingling of the extremities; discoloration of the hands and feet; subjective pulsations and "flashes" of heat and cold; excessive sweating, polyuria, and the like. These phenomena in their milder or in their severer forms are more common in women and are often associated with disturbances of menstruation; the familiar symptoms of the "change of life" belong in this category.

Among other associations having an etiologic suggestiveness are abnormity of the thyroid gland, gastric and intestinal disturbances, gout and lithemia, rheumatism and rheumatoid arthritis, hay fever, neurasthenia, hysteria and cutaneous pigmentation. The phenomena may be intermittent and capable of artificial reproduction, and we thus find as their principal exciting causes, toxins (both autogenetic and heterogenetic), temperature changes, and emotional disturbances. In most cases, of whatever origin, a distinct temperature relation can be made out, the patient feeling better or worse in summer or winter, respectively.

As a whole the phenomena are merely exaggerations, in duration and degree, of the effects of the same kinds of exciting influences upon normal individuals, or to put it another way, the same phenomena which in the cases under consideration are interpreted as evidences of disease, may occur transiently in normal individuals under similar exciting causes of greater magnitude. Thus severe cold may cause in a healthy person phenomena much like those which, excited by a minor cause, we call Raynaud's disease; and intense heat, anger, fright, sexual excitement, produce many of the phenomena we find among the symptoms of Graves' disease. Familiar illustrations of the minor varieties are the attacks of urticaria, which in some individuals result from the ingestion of foods that most persons can take with impunity, and the eruptions and edemas that mark so-called idiosyncrasies to drugs. Here, too, we find an interesting connection with angio-neurotic edema, which in some of my cases can be produced at will, in certain localities, by moderate trauma, for example as a slap on the lips; and in this as in other phases of the general subject the influence of family and of heredity is marked. In some cases the phenomena of irregular and excessive dilatation, in others those of irregular and excessive contraction of vessels predominate; in all some phenomena of both kinds are found; in all there are paroxysmal exacerbations: in some normality apparently prevailed during the interval. Whether the group of affections thus included would or would not form in rigorous nosologic classification and order, whatever the exact mechanism of the symptoms or the immediate exciting influence, the fundamental cause is apparently a constitutional vice of nutitrition, an instability in the nervous centers governing the cardio-vascular balance; and we are led to direct our therapeutic measures accordingly.

Confining our attention now to those cases which present phenomena chiefly referable to vascular dilatation, we find that the most severe of these have for their usual concomitants, enlargement of the thyroid gland and protrusion of the eye-balls. In nearly every case tremor is associated with the tachycardia, exophthalmus and goiter, which Graves and Basedow described as the triad, characterizing the affection to which their names have been given; and in all of the cases which I have studied since 1892, I have found dermographism, factitious urticaria, and the peculiar crescentic markings upon the nails, to which I called attention in my first paper on this subject.

The statistics of treatment in exophthalmic goiter are confusing to the student. Some cases recover without treatment, some fail to recover under any treatment, and many cases of recovery or great improvement are reported from the most varied forms of treatment. In order to be made valuable the recorded statistics need close analysis as to many facts, some of which are not commonly observed. We should include not only heredity, age, sex and apparent exciting causes, but the physical and mental temperament of the individual, and such other relations of morbidity and susceptibility to therapeutic measures, as may be needed to give a complete picture. Let statistics be what they may, few among those who have had large experience with Graves' disease will be content to trust to spontaneous recovery, or will fail to draw a conclusion of cause and effect between the treatment instituted and the results following.

It has been my fortune to have had a comparatively large number of cases of exophthalmic goiter under observation, and I have seen recovery and partial recovery from various methods of treatment, which have, however, agreed in that they were devoted to the removal of excretion and intestinal antisepsis, of toxins that might be circulating in the blood; to the soothing of the excited nervous system by rest; and to the restoration of cardio-vascular tone by appropriate medication or other remedial influence, *i. e.*, galvanism or the application of cold.

In common with many other observers, I was led to the use of thyroid extract experimentally, when that substance was first introduced into practical medicine by British observers, and contrary to the experience of most others, and to my own experience in other cases, one of my patients so improved that he refused to remain longer in the hospital. He was under treatment from January to March, 1893.

Dr. David Owen of Manchester, published the report of a case in which wonderful improvement followed the supposed ingestion of thyroid gland; but further investigation showed that the butcher had been supplying his patient not with thyroid gland but with thymus. In my case the preparation was furnished by Messrs Parke, Davis & Co., while they were still experimenting as to methods, and before they had placed it on the market, and they assured me that no such mistake had occurred. Patton's partial recovery, therefore, remains unexplained.

I should also mention in this connection, the good effect of thyroid extract in a case of marked vasomotor ataxia, characterized by right or left hemicrania, with temporary numbness and paresis of the opposite arm, and great pallor of the face, occurring at first spontaneously, but now only after certain indiscretions in meat or drink, in a man whose mother had had exophthalmic goiter. The continuous administration of a small dose of thyroid extract will ensure complete absence of attacks; a large dose will cause headache and vertigo, with opposite symptoms, namely flushing and warmth of the face; while nitroglycerin or amyl nitrite is required in the paroxysm. As a rule thyroid extract benefits that group of patients who feel best during the summer, and injures those whose worst symptoms occur in warm weather.

From Owen's experience with thymus; from almost universal experience that thyroid is harmful to patients with Graves' disease, exaggerating the symptoms; from the fact that tachycardia and vascular unbalance, even to fatal issue, may be produced from incautious use of thyroid in myxedema; from the frequent persistence of the thymus in akromegaly, indicating some yet unexplained reciprocal relation between this gland and the thyroid, I was led to the deliberate administration of thymus to patients with exophthalmic goiter and minor degrees of vasomotor ataxia.

I have so treated twelve cases of pronounced Graves' disease. I present a few cases in which the improvement has been remarkably great. In Mrs. B. (May 5, 1896) the goiter has almost entirely disappeared, the exophthalmus is scarcely perceptiple, the heart is quiet, concomitant rheumatoid arthritis has much improved, pain being almost gone, and the nervousness and trembling, which was her principal complaint, is entirely gone. (See case of Mrs. McD.)

In Mrs. McE. (Aug. 7, 1895) the goiter has been reduced about two-thirds, the Addisonian color has been much lightened, the nervousness and sleeplessness has disappeared. In a third case, Miss L., a patient referred by my friend and colleague Dr. S. D. Risley, the improvement is equally great but less striking; inasmuch as the goiter never was very large nor the exophthalmus prominent. Tachycardia and nervousness have disappeared and general nutrition has been greatly benefited. In a fourth case, Mrs. McD., quite severe, which I saw in consultation with Dr. Albert M. Eaton of this city, there were many interesting diagnostic and etiologic points. After an operation for ovarian cyst, followed by sepsis, the patient complained of severe cardiac pain and dyspnea, and there was observed excessive rapidity of pulse. At the time I saw her she had been confined to her bed for some months: goiter and exophthalmus were evident. Thymus extract was presented and the patient was so far reduced after treatment that she was able to follow her accustomed duties. A relapse suddenly followed and it was found that the druggist had given thyroid instead of thymus. I may add that Mrs. E. experienced a similar relapse from the same cause, the goiter enlarging and becoming quite hard and tense like a cyst.

Upon return to thymus there was renewed improvement. Although the dose given has been throughout too small, the patient refusing to take the quantity prescribed, Dr. Eaton tells me that the goiter is almost gone, the dyspnea entirely gone, the heart quiet and regular except on unusual exertion, and the patient able to go shopping.

In two other cases of genuine Graves' disease, and in some twenty or thirty cases of minor varieties of vasomotor ataxia, of the relaxing variety, I have seen equally good results. Dr. Hector Mackenzie recently reported twenty cases of exophthalmic goiter treated with thymus without benefit.

More recently, the physiologic experiments showing that in the adrenal secretion there exists a natural raiser of blood pressure, probably active by constriction of the vessels; together with the fact that Addisonian pigmentation occurs in some cases of Graves' disease; and that exceptional cases are met with in which exophthalmic goiter and Addison's disease are alternate diagnoses, suggested the use of adrenal extract in the treatment of this affection. Since I instituted it, at the Philadelphia Polyclinic, I have seen publications of similar observations elsewhere. Two patients disappeared from observation before any conclusion could be drawn, except that they could take remedy without ill effect. I therefore reverted to an old patient who would remain under observation. I refer to Mrs. B., whom I have already shown as an example of the good results of thymus treatment. She had been absent from the clinic for six months, during which time she had been without medicine. She returned complaining of a recent return of nervousness and of pain in the finger joints. We placed her under treatment with adrenal extract, which she is still taking, and, she thinks, with equally good effect in maintaining and even increasing her improvement. The case lacks conclusiveness because of the great gain previously made under thymus treatment.

In the case of Mrs. McD. before reported, suprarenal dosing failed to give good results, but increased the headache and apparently caused increased excretion of uric acid (brick dust sediment appearing), bloody sputum and vertigo. I present two other patients, Mr. S. and Mrs. M., both of which have been treated only with suprarenal extract. They were never marked cases as to goiter or exophthalmus. Mrs. M. (Jan. 8, 1897), had a decided tremor which has been much reduced, while the cardio-vascular and neurotic phenomena have greatly improved in both.

Miss K. is a marked case. Her improvement is chiefly as to nervous and vascular phenomena and general nutrition. The pulse is quieter, the breathlessness relieved. She says that the goiter is smaller and we are all sure that the exophthalmus is much less, but unfortunately accurate measurement was not made when she first appeared.

Mr. H. is a patient presented for the sake of fairness; he appeared at the clinic the same day as Mrs. K., and was just as marked a case. We presented adrenals and he disappeared until this week; has much improved, but has been for the most part without treatment.

Miss F. is presented to show the effect of a different remedy—picrotoxin. Her improvement is equally great.

From the clinical observations, including sphygmographic tracings made on the various cases I have thus far studied, I conclude that thymus extract will in many cases of exophthalmic goiter, improve nutrition, mitigate nervous disturbances, reduce exophthalmus, greatly reduce goiter, and moderately quiet the heart and restore vascular tone, completely accomplishing this in milder cases; while adrenal extract seems to have greater influence upon the circulation and less effect upon the thyroid and ocular symptoms. We are making studies upon the blood and secretions, which are not sufficiently advanced for publication. I do not believe that either of these remedies or any other remedy removes the fundamental, constitutional, idiosyncratic instability of the toxic mechanism of the circulation; but I do believe that they are competent in the one case—thymus—chiefly by an antitoxic action, to counteract the exciting influences, and in the other case—adrenal—chiefly by opposing action upon the circulation to neutralize the effect of those influences. *Probably both share both these actions in some degree, and I should expect the best results to follow their combined administration.*

THE IMPORTANCE OF THE HABIT OF PROGNOSIS IN THE DEVELOPMENT OF THE INDIVIDUAL PHYSICIAN.

Read in the Section on Practice of Medicine, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY LOUIS FAUGÈRES, BISHOP, A.M., M.D.

Late House Physician St. Luke's Hospital; Chairman of the Section on General Medicine of the New York Academy of Medicine, Secretary of the Section on State Medicine of the American Medical Association; Member of the Neurological Society, etc.

NEW YORK CITY.

It is the duty of a physician to himself and to his patients, not only to be well informed, but it is also to look out for new methods that tend to the best possible training for his work. Habits, good and bad, are the relentless masters of our lives and actions. Powerful as they are for evil they are equally potent for good if seized upon, developed and directed. Habits of mind and thought are just as much habits as those pertaining to the physical nature.

Now there is a particular attitude in approaching a medical case that would seem, more than almost any other, to lead to sound judgments and judicious management, the attitude that takes account of not only present conditions, but discounts them by the probable future. It not only considers what the course of disease will be, if treated, but its course if untreated or treated in a different way. This we may call the habit of prognosis, and upon it must be based all thoroughly judicious and honest therapeutics.

Medicine is a science and at the same time an art. Indeed it is a combination of many sciences and many arts. Thus there is the science of pathology, the science of chemistry, the art of treatment, the art of feeding, the science of diagnosis and the art of prognosis. The power of prognosis is at the same time an acquirement and a gift. Like all other faculties it is improved by exercise and increased by cultivation. Its basis, though largely personal experience, is equally found in a knowledge of medical literature. Thus the experience of a long lifetime may not afford as good a basis for prognosis in a particular case as an hour intelligently spent in a medical library. The faculty is best cultivated by the exercise of the habit of forming, with care and study, the most definite possible prognosis in every case that comes under observation, and then faithfully promulgating it to those who have a right to such an opinion. The first step in prognosis is accurate diagnosis, not the mere naming of disease so that it may fall within the list of diseases such as are found in the index of a text-book of medicine, but the placing of a case in a particular group of a particular variety of the disease. Then, by recalling from personal experience and searching literature, as many parallel cases as possible are summoned as witnesses; then the mathematical theory of chances and probabilities is brought to bear and the conclusion is reached. It seems strange, at first sight, that in art so varied as medicine, mathematics should have any possible bearing, and yet in the almost parallel science of life insurance, mathematics has found one of its most useful applications. The life insurance company can not say with certainty that a certain man of 40 years of age will live so many years, but it can say with very close certainty of a particular group of ten thousand men, that so many will be alive and so many will be dead in ten years. It is the same way with the prognosis of particular classes of disease. If we can assemble, from personal experience and experience as recorded in literature, a group of one hundred of whom ninety have survived a year, we can give a prognosis in the particular case, all attending circumstances being carefully considered, that the chances of survival for a year are nine out of the ten; in the same way is the prognosis of the time of recovery in particular cases. If we have summoned to our aid, truthfully, a group of parallel cases, and have intelligently discounted particular surrounding circumstances, we can give a prognosis as to the time of recovery which will be correct six times out of seven; seven times out of eight; eight times out of nine, or nine times out of ten, according to the breadth of our knowledge, and the accuracy of our observation.

The value of the constant habit of prognosis can not but be very great to the individual physician. It will give him encouragement and hope in many a desperate case, and save him from undue disappointment when the inevitable laws of nature have run their relentless course. He who has mastered the art of prognosis stands, as it were, on the summit of a mountain where he can see beyond his fellows who have not climbed up the steep and laborious path. Observe the calm philosophy of this man, who with his eye ever on the future, neither urges rash measures nor advocates undue delay, and who is not carried away by the promises of false prophets. He is not deceived by the bright coloring given to the landscape, by the passing meteor, into the belief that the force of all nature has been permanently changed.

The ideal opportunity for the study of therapeutics would be by the treatment of exactly parallel cases by several methods, and their comparison at the same time with cases untreated and pursuing the natural course of the disease. These conditions are only found in rare instances and in large hospitals. Usually, if cases are treated by various methods, it is at different times and the mind pictures of older cases are dim and indistinct. The untreated case is hardly to be found. It is in supplying the place of untreated cases that the development of the habit of prognosis finds its most important place. By careful analysis of the case in hand, by summoning to one's use the records of previous cases accurately observed, by discounting the treatment of one by the treatment of another, and observing the course and outcome under various conditions, one may construct an *ideal case similar to the* one in hand, but with its history continued into the future. This ideal case supplies a prognosis by which to be guided in the selection of therapeutic measures, the judgment of their efficacy and the expectation as to cure.

Prognosis is often enough modified by the wealth or poverty of the patient, by his character, by his hopefulness or depression, and by a thousand other things that arise in the individual case, but the discussion of more exact methods of prognosis must find a place elsewhere. What would be emphasized is this, that every physician should form the habit of constructing a well-founded judgment as to the future course of any case of which he seriously undertakes the care. With this judgment he should constantly compare the course of this case while under treatment, and honestly acknowlege the futility of useless therapeutics as well as the modifying influence of really valuable measures.

The remark is often made that prognosis is not worth while, that it does not influence the outcome of the case, that a wrong prognosis is apt to bring disrepute, and that it is better to treat the case from day to day, and leave *the result with Providence.* This is the reasoning of those who take a superficial, and as it were, a symptomatic view of disease; is the reasoning begotten of intellectual laziness, timidity, and self-conceit. How much more moral courage does the physician exhibit, who throwing his whole intellectual acumen into a case, carefully studies all the circumstances, carefully summons to his aid his own experience, and that of others, and then having given the results of his very best work, is willing to stake his reputation on the result. Even from a lower standpoint, that of professional reputation and success, this in the long run pays best. The greatest physicians in all times have made errors, but the consultants, the men whose counsel is sought in time of great danger, have been men of strong characteristics, who were able and willing to form an opinion and to stand faithfully by that opinion when formed. The mistakes of such men are apt to be condoned while their successes become a glory to their profession, which obscure practitioners are proud to promulgate.

REPORT ON THE TREATMENT OF PULMONARY TUBERCULOSIS.

Read in the Section on Practice of Medicine, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4.

BY DeLANCEY ROCHESTER, M.D.
ADJUNCT PROFESSOR OF THE PRINCIPLES AND PRACTICE OF MEDICINE MEDICAL DEPARTMENT, UNIVERSITY OF BUFFALO.
BUFFALO, N. Y.

This report covers in most of the cases a period of about eight months, in some of the cases a period of nearly two years.

The various remedies, upon the use of which the report is made, are Edson's aseptolin, Paquin's tubercle antitoxin and Vaughan's nuclein. In all cases where the stomach does not rebel, cod liver oil was also used. Alcoholic stimulants have not been used, except as temporarily called for. Locally, inhalations, sprays and insufflations consisting of iodoform in ether and in powder, menthol in albolene, essence of peppermint and a mixture of acetanilid, carbolic acid and glycerite of tar according to the formula of Dr. R. P. Lincoln of New York City, have been used. In all cases reported the tubercle bacillus was found in the sputum.

Following is the detailed statement of cases treated by aseptolin (which is a solution containing 3 per cent. of absolute phenol and 0.01 per cent. of pilocarpin-phenyl-hydroxid). This is in no sense an antitoxin but is designed, according to Dr. Edson's statement, "to greatly reinforce the natural antiseptic power of the blood."

Case 1.—D. N., male, age 47, nativity United States.

May 4, 1896. Previous history.—Has been running down for nearly a year; coughing and raising considerable; vomiting frequently; having irregular chills followed by high fever and night sweats; weight at this date 119 pounds. Tubercular infiltration of right upper lobe; aseptolin treatment begun.

May 21. Since the treatment began patient feels better, appetite has improved, no chills or vomiting, temperature has not gone above 100 F., no night sweats, weight 121 pounds. Pulmonary condition unchanged. Supply of aseptolin gave out and treatment was omitted until June 19 when general and local conditions were not different from previous record. Weight 124 pounds.

July 16. During last month there have occurred two hemoptyses and treatment was omitted for five to seven days each time. The upper lobe of right lung shows distinct sign of softening, and cough and expectoration have greatly increased in amount, but temperature has not gone above 98.5; there have been no chills, sweats or vomiting and the weight is 129 pounds.

August 13. No change in patient's condition except that he has lost appetite, feels weak and dispirited and physical examination reveals extension of the area of softening. Weight 131 pounds.

August 23. Profuse hemorrhage; weak and discouraged; weight 130½ pounds.

October 2. Since last record patient has had two more hemorrhages, not so severe. and none since September 4; feels a little stronger and in better spirits. Temperature has reached 100 several times. Pulmonary condition not materially changed. Weight 131 pounds.

October 20. During last three weeks patient has felt worse, there has been increase in cough and expectoration and there has been vomiting (caused generally by the iodoform spray). Physical examination reveals infiltration in *left* upper lobe and distinct cavity in right upper lobe. Weight 129 pounds.

December 1. Patient's general condition has improved somewhat, vomiting has stopped, cough is not so distressing, but temperature has ranged rather above 100, reaching 101 several times. Physical examination shows steady advance of the tubercular process in both lungs. Weight 129¼ pounds. Patient complained bitterly of the pain of the injections and treatment was stopped.

Case 2.—H. K., male, aged 37, nativity United States. Aseptolin.

July 15, 1896. Previous history.—For eighteen months there has been progressively increasing anemia, and malaise, marked anorexia, night sweats and occasional hemoptyses, considerable dyspnea, lack of sleep and depression of spirits. There was consolidation of upper left lobe and some infiltration throughout the rest of the left lung. The temperature frequently reached 101 and sometimes fell as low as 97. The respirations ranged in the neighborhood of 30 and the pulse from 80 to 100. The weight record of this case for the first three months was lost. Cough was very troublesome, almost continuous, and there was a large amount of sputum raised.

August 13. During the last month there has been great improvement in all respects; appetite better; sleeps well; cough and expectoration decreased; dyspnea continues; no night sweats since July 18. Temperature has not gone above 99.2.

September 12. Condition has remained about the same.

October 13. Improvement continues in all respects, except that cough and expectoration have increased and there is evidence, on physical examination, of infiltration at right apex in addition to that existing in left lung which has not changed. Weight 130 pounds.

November 10. Improvement continues. Weight 134½ pounds.

December 8. Improvement continues. Weight 138 pounds; cough and sputum diminishing.

January 12, 1897. Continued improvement in all respects. Weight 142 pounds. Aseptolin stopped on account of pain of injections.

February 2. Not quite so well. Weight 139½ pounds.

Case 3.—F. S., male, age 31, nativity United States. Aseptolin.

May 4, 1896. Previous history.—For six months gradual failure in strength and health, anorexia, anemia, marked cough, profuse expectoration, afternoon fever, profuse night sweats. Tubercular infiltration of upper and middle lobes of right lung. Weight 92 pounds. Aseptolin begun.

May 21. Appetite improved, temperature lower (100.8 highest), no night sweats. Cough still severe and sputum still profuse. Marked dyspnea. Weight 92 pounds. Aseptolin omitted until

June 19. During this month improvement continued and cough became less troublesome. Pulmonary condition not changed. Weight 98 pounds.

August 23. During last month there has been falling off of appetite and disappearance of previous sense of improvement. Cough and expectoration have again increased and the dyspnea is more marked. There has been an extension of the diseased process downward to the lower lobe of right lung. Weight 100 pounds.

September 2. Aseptolin omitted on account of soreness of abdomen. Temperature has again increased and patient feels weak and dispirited, suffers greatly from dyspnea and complains of pain in left chest. Weight 101 pounds.

October 2. Aseptolin resumed. Patient's general condition not materially changed except that soreness in abdominal walls is less. There is evidence of infiltration of entire right lung and of left apex. Weight 98 pounds.

November 8. Patient has gradually and steadily failed in all respects, general and local. There is infiltration of entire right lung and cavity in left upper lobe surrounded by zone of breaking down lung. Weight 91 pounds. Aseptolin stopped.

Case 4.—T. D., male, native of Ireland. Aseptolin.

May 2, 1896. Sickness dates back six years. During this time there have been periods of long quiescence with occasional outbursts of cough, fever, etc. These have gradually increased in frequency. Patient is anemic and has no appetite, feels very weak, suffers from great dyspnea. There is evidence of consolidation of upper left lobe, and scattered areas of broncho-pneumonia through rest of left lung and slight bronchitis in upper right. Coughs a great deal with not very much sputum. Temperature not above 100, pulse 100, respiration about 30, weight 130 pounds.

May 21. During the last three weeks temperature has not gone above 99, and night sweats have ceased. Otherwise, no change in patient's condition. Weight 128 pounds. Aseptolin omitted until

June 19. During last month no change in patient's condition. Weight 126½ pounds.

July 24. Some general improvement, sleeps well, appetite good, no sweats, cough and expectoration less. Dyspnea marked. Weight 126 pounds.

August 13. General condition not changed. Weight 122½ pounds.

October 13. During last two months there has been no material change in general condition, but the disease in lungs has progressed so that there is now cavity in upper left lobe and infiltration in lower left, with bronchitis in right lung. Weight 123 pounds. Aseptolin stopped on account of pain of injection.

December 8. No change in general condition nor in pulmonary condition. Weight 119 pounds.

Case 5.—H. G., male, age 54, nativity United States. Aseptolin.

May 3, 1896. Previous history.—For a year patient has had cough, with slight expectoration, frequent asthmatic attacks, very slight fever occasionally, no night sweats. Has poor appetite, is anemic, sleeps poorly, feels weak and debilitated. Has general bronchitis and emphysema and infiltration of right upper lobe and left apex. Temperature ranges from 96.5 to 98.5, pulse 60 to 90, and respiration 20 to 30. Weight 115 pounds. Aseptolin begun.

May 21. No change in condition except that he coughs and raises a great deal now. Weight 149 pounds. Aseptolin omitted until

June 19. No change. Weight 150 pounds.

July 24. During last month sleeps well; appetite not so good, does not feel as well.

August 23. No change except that cough and expectoration are increasing. Dyspnea somewhat relieved by quebracho. Weight 144½ pounds.

September 1. No change. Weight 146 pounds. Aseptolin stopped on account of soreness of abdomen.

October 6. During the last month patient has felt better, appetite improved, dyspnea not so marked, but cough and expectoration continue to increase. Weight 143½ pounds. Aseptolin resumed

November 17. During last six weeks patient has become worse in all respects. The local conditions have not improved. The cough continues severe and the expectoration very profuse. Temperature has reached 100 on several occasions, and once fell to 96. Weight 138 pounds. Aseptolin stopped. On December 1 weight had fallen to 135½ pounds.

February 2. Patient has improved in all respects during last two months. Weight 139½ pounds.

Case 6—J. M., male, age 50, English parentage. Aseptolin.

August 1. Previous history.—Has had cough and occasional diarrhea for one year. In December, 1895, had very severe cough. Since then has lost forty pounds in weight, coughs considerable, sputum thick and tenacious and considerable in quantity. Temperature does not go above 100. During last two weeks has suffered from night sweats. The left apex and the right upper lobe are infiltrated. Weight 150 pounds. Aseptolin begun.

August 23. Pulse stronger, no night sweats, but appetite is poor and he is kept awake by coughing. Has developed slight laryngitis. Weight 154½ pounds.

September 12. During last three weeks has had some diarrhea; laryngitis has improved. Developed albuminuria with markedly diminished urine. Aseptolin stopped. Weight 152 pounds.

October 9. After the first diminution in the amount of urine secreted, there came a marked increase in amount of urine, and although the albuminuria remained, the polyuria became extreme; during last two months of his life patient passed from 2000 to 5000 c.c. of urine in twenty-four hours, containing from 20 to 50 gm. of urea, *though of low sp. gr.*, and containing albumin in abundance, and some casts. Weight 157 pounds. December 19, he died, having been comatose for twenty-four hours before death. During last two weeks of his life he had two attacks of severe gastritis and developed corneal ulcers in both eyes. His weight two weeks before death was 136½ pounds. No autopsy.

Case 7.—R. B., male, age 35, nativity United States. Aseptolin.

August 12, 1896.—Previous history.—For six or seven months has suffered from cough and expectoration, chills, fever and night sweats. Loss of appetite, loss of weight, great weakness, marked dyspnea, respirations have ranged between 30 and 40, pulse 80 to 120 and temperature 97 to 102 degrees. There is infiltration of left apex, infiltration and softening in upper lobe of right lung with bronchitis in middle right lobe. Cough and expectoration slight. Weight 100 pounds. Aseptolin begun.

September 12. No material change except that night sweats have ceased and temperature is ranging nearly a degree lower at its maximum, cough and expectoration increasing.

October 13. During last month there has been a steady decline in all respects, except that the temperature has ranged lower and the night sweats have not returned. Patient has been troubled greatly with sleeplessness and nightmare. The diseased processes in the lungs have progressed quite rapidly and the cough and expectoration increased in a marked degree. Weight 91 pounds. October 16, patient died.

In addition to these seven tabulated cases, two other
cases were treated with aseptolin although they were
rapidly advancing in tubercular destruction of the
lungs. In neither case was any benefit observed from
the treatment, either locally or generally. The treat-
ment was stopped after two months. Both cases
died. Except in the cases that died the treatment
was continued from four to six months. Of the
nine cases treated, in seven the night sweats ceased
entirely and the temperature range was lower during
treatment than before the treatment was begun; in
one (case No. 2), there was a gain in weight, and im-
provement in all general symptoms, appetite increased,
sweats ceased, temperature fell to normal or half
degree above, but the local conditions as revealed by
physical examination did not change though the
cough and expectoration were much lessened; in one
other (case No. 1), there was gain in weight for four
months. sweats ceased, appetite improved, temperature
did not range above 100 degrees F. but the local
changes in the lungs progressed, cough and expector-
ation increased, there were several hemorrhages and
during last two months patient began to lose in weight,
appetite failed and temperature began to range higher.
In all of the other cases there was progressive loss
in weight, marked progress in the local disease, and no
improvement in any symptoms except in the cessa-
tion of the night sweats and the somewhat lower range
of temperature.

Of the nine cases treated four died, two from two to three months after treatment had been stopped, one during treatment and one, I think, because of the treatment. This case (No. 6), deserves especial mention. In this case as in all others, careful examination of the twenty-four hours' excretion of urine was made before treatment was begun. The kidneys were in normal condition. (The urine in all cases was examined every day.) Treatment in this case was begun August 1. On September 12 albuminuria and almost complete suppression of urine occurred. Treatment was immediately stopped. Patient had gained four and one-half pounds during first three weeks of treatment and lost two and one-half during last three weeks. During the month following the stopping of treatment he gained five pounds, although the albuminuria persisted and gradually increased. About October 1, three weeks after aseptolin had been stopped, in addition to the albuminuria he developed a marked polyuria which lasted until his death, which occurred December 19. The amount of urine voided daily during the last two months of his life was from 2000 to 5000 c.c., containing from 20 to 50 gm. of urea and a large amount of albumin and hyaline, granular and epithelial casts in abundance. During the last two weeks of life he was confined to bed, had three attacks of severe gastritis and developed corneal ulcers in both eyes. He died in a state of coma. Autopsy was not secured.

In no case can I report a cure. In judging of the value of aseptolin in these cases we must bear in mind the fact, that the treatment was begun in the early summer and continued through the summer and somewhat into autumn and early winter; that the improvement in those cases in which improvement was noted, took place during the summer, while the weather was such as permitted out-of-door life, but that when the weather grew more inclement and out-of-door life was interfered with, the improvement did not continue. The one thing that impressed me as of value in the use of aseptolin was that in all cases the night sweats were promptly stopped and did *not* recur. In most cases also, the range of temperature was lowered. As these same results can be obtained by other measures which do not carry with them the possibility of producing an albuminuria and even a nephritis and death, I question whether the use of so dangerous a remedy is justifiable.

The next series of cases I have to report is a series of cases treated with Paquin's tubercle antitoxin.

Case 1.—D. M. was Case 1 of aseptolin series. Aseptolin treatment had been stopped two weeks and patient gained in appetite, ability to sleep, and slightly in weight. Temperature ranged from 98 to 100.5 degrees, pulse 80 to 100, respiration 20 to 28. Weight 130½ pounds.

December 12, 1896. Tubercle antitoxin begun; there is infiltration in upper left, cavity in upper right.

January 4, 1897. Patient feels very badly, has steadily gone
downward since treatment was begun, great pain was produced
by the injection; they were followed by a marked dermatitis
and by swelling of left axillary glands, headache, gastric pain,
anorexia, diarrhea, pain and stiffness in limbs. Temperature
ranged during this month from 97 to 102.5 degrees, pulse 80 to
110, respiration 22 to 28. Infiltration in upper left remained
inactive but there was marked increase in softening about cav-
ity in upper right. Cough and sputum greatly increased.
Weight 129½ pounds. Treatment stopped.
January 27. Headache and ache in bones have disappeared,
sleeps well and feels better. Weight 126½ pounds.
Case 2.—F. S. This case had also been an aseptolin (case
No. 3), and had not improved since aseptolin stopped.
December 14, 1896, had held his own in weight in spite of three
small hemorrhages. Temperature has varied between 98 and
100, pulse between 88 and 100, respiration 20 to 24, cough and

sputum have diminished, appetite is good, sleeps well, no night sweats, weight 91½ pounds. Infiltration of left apex and of right upper lobe with bronchitis in right middle lobe. Tubercle antitoxin begun.

January 4, 1897. During the last month patient has failed in all respects; shortly after serum treatment was begun, he began vomiting severely, and has had one severe hemorrhage. Cough and sputum have both increased. Injection set up dermatitis and caused swelling of axillary glands; the infiltration has proceeded downward from left apex into entire upper left lobe, softening has begun in upper right and infiltration has progressed into middle right. Temperature has ranged from 97 to 101.4 degrees; pulse 80 to 120, respiration 28 to 40, weight 88¾ pounds. Patient is distinctly worse in all respects. Treatment stopped.

Case 3.—T. D. This case also has been on aseptolin (case No. 4), and had not improved. Aseptolin stopped October 13. Since then patient has lost three pounds in weight but has held his own in other respects. Appetite is fair, sleeps well, feels pretty well, coughs and raises considerable. Temperature 98 to 100 degrees, pulse 70 to 100, respiration 20 to 30. There is infiltration in upper left and in middle right, and cavity in upper right. Tubercle antitoxin begun Dec. 14, 1896,

January 5, 1897. During last month patient has lost ground in all points; feels very badly, appetite gone, sleeps poorly, severe and continuous headache, dermatitis marked, cough and expectoration markedly increased; condition of the left lung remains the same, but there has been marked increase in the softening about cavity in right lung. Temperature 97 to 100 degrees, pulse 80 to 110, respiration 20 to 30. Treatment stopped.

February 2. Patient continued to lose weight for three weeks after treatment stopped. Since then has gained a little. Headache ceased; feels, sleeps and eats better. Cough not changed.

Case 4.—M. R., male, age 34, native of Ireland. Tubercle antitoxin. Jan. 8, 1897. Previous history.—Negative until in July 1896, when he began to have a slight cough, loss in weight and strength, and suffer from pain in side and chest. Is anemic and has had occasional night sweats. Temperature has ranged from 99 to 101 degrees, pulse 100 to 110, respiration 20 to 30. There is infiltration of left upper lobe as far down as the level of the second rib in front, and as far as the spine of the scapula behind. Considerable cough and expectoration. Weight 120 pounds. Antitoxin treatment begun.

February 2. Patient felt better for first two weeks, and gained two pounds in weight which he lost in the third week, but gained one back in next week. The pain in his chest disappeared in first two weeks, but returned with greater severity during last three weeks; he also developed pain in his left hip and his stomach. During last three weeks has vomited nearly every day, his appetite has failed and the cough and expectoration have increased. His temperature has ranged from 98 to 102 degrees, pulse 90 to 120, respiration 22 to 34; he has had three severe night sweats. Softening has developed in left upper lobe and there has been some extension of disease downward. There has been no dermatitis or swelling of lymph gands. Weight 121 pounds. Treatment stopped.

Case 5.—P. R., male age 54, native of Ireland. Tubercle antitoxin. Previous history: Pneumonia five years ago; cough for two years: hemorrhage one year ago. In September 1896, had another hemorrhage and began to run down in weight and strength. Entered hospital Oct. 14, 1896. Fair appetite, sleep poor, night sweats, occasional diarrhea. Temperature 97.5 to 98.8 degrees, pulse 90 to 100, respiration 24 to 32. Cough and expectoration considerable, sputum often blood tinged. Scattered areas of broncho-pneumonia in both lungs, together with considerable emphysema; cavity in upper right lobe. Weight 125 pounds.

December 12, 1896. Under hygienic measures, good diet and creasote, patient has gained nine pounds in weight, hemorrhages have ceased, night sweats less severe and less frequent. Temperature 98 to 98.5 degrees, pulse 90 to 100, respiration 24 to 30 Areas of broncho-pneumonia have materially diminished, otherwise pulmonary condition is the same. Weight 134 pounds. Tubercle antitoxin begun.

January 4, 1897. From the time injections were begun patient began to feel badly, aching and numbness in limbs and back, headache, bones ache with return of night sweats in great severity, cough and sputum increased greatly in amount and hemorrhages again began. Temperature 97 to 100 degrees, pulse 80 to 120, respiration 24 to 36. Areas of broncho-pneumonia again increased and there developed considerable softening about cavity. Weight 129 pounds. Treatment stopped.

From this time on patient continued to grow worse in all respects; hemorrhages continued, sweats, fever and broncho-pneumonia increased and softening extended; patient finally died March 1, 1897.

I have three other cases treated with tubercle antitoxin to report. One Miss B., age 17, American of German descent. This case I first saw in September, 1896. She at that time was having high fever in the afternoon, night sweats, severe cough, considerable expectoration, poor appetite and occasional diarrhea. She was not weighed. I put her upon Vaughan's 1 per cent. solution of yeast nuclein. She did well upon it, appetite improving, cough diminishing and sweats becoming much less frequent and fever also subsiding to a marked degree. The local condition, which at first showed cavity in right upper lobe, infiltration in rest of right lung and in left upper lobe improved to a considerable degree, the lower lobe of right clearing up almost entirely, the cavity in upper right remaining, but apparently not extending, the infiltration in upper left remaining about the same.

In spite of this improvement I foolishly changed to the antitoxin in December, beginning the injections on December 10. The injections of tubercle antitoxin were very painful, a marked dermatitis occurred and swelling of the axillary lymph nodes. Her general health suffered greatly. The afternoon fever returned, the sweats again became marked, appetite diminished and after about three weeks' treatment the girl declined further treatment by injection of any kind, even declining to go back to the use of nuclein. The local condition took a new start in progress of disease, the cavity on the right side enlarged, the left upper lobe also began to break down and areas of broncho-pneumonia showed themselves in lower lobes of both lungs.

The cases so far reported were undoubtedly cases of mixed infection and it may well be said that good results from a specific antitoxin should not be looked for in such cases. The next two cases were apparently pure tuberculosis. The first, David D., a young man 20 years of age, tubercular family history in grandparent and aunt, consulted me first Dec. 13, 1896, on account of cough. Physical examination of the chest revealed nothing, but chest tending to pigeon shape and poor development. Examination of throat showed enlarged tonsils, especially the right one, and a reddening of the vocal bands with some edema of false cords. He was referred to a throat specialist who treated the laryngeal condition and a diseased nasal condition without much relief to cough. Patient also began to vomit considerably at this time after severe attacks of coughing. Almost no expectoration, the little that was brought up being mostly glairy mucus not containing tubercule bacilli. On December 31 I amputated the right tonsil. For nearly a week after this the cough was much better. It then began again. His voice became quite hoarse and at times he could only speak in a whisper. Examination of the larynx on Jan. 26, 1897, revealed tubercular infiltration of the larynx—ulceration of the free margin and superior surfaces of both vocal bands over the anterior halves of the membranous portions—swelling of the arytenoids prevents complete closure of glottis; about this same time physical examination revealed some infiltration of right apex but no softening. Not until a week later were tubercle bacilli found in the sputum, which remained very scanty. On January 26 began injection of Paquin's tubercle antitoxin, and gave them daily for thirty-two days, patient growing steadily worse and the injections producing such severe pain, lasting for from four to eight hours, that the patient dreaded the coming of another day. The local condition of the lung did not improve, on the contrary, began to show distinct signs of breaking down. Patient gained three pounds for two weeks and then lost nearly three. On February 26 the injections were stopped, certainly having done no good and possibly having been productive of harm.

The last case of those treated with tubercule antitoxin was a man from whom a tubercular testicle had been removed two months before. This case presented no evidence of pulmonary tuberculosis, but presented enormously enlarged lymph nodes in the groins and extending into the pelvis and some distance into the abdominal cavity. He was put on the serum injections on Dec. 12, 1896. He suffered no inconvenience from them and gained in weight and strength. The injections were continued until April 22, 1897, when he left the hospital much improved in general health, apparently not injured by the injections, though at one time they had to be omitted on account of soreness produced, but were begun again in a week. There was, however no change observed in the size or contour of the glands already involved, but on the other hand there was no further extension and involvement of other glands or organs.

The conclusions to which I have come in regard to Paquin's tubercle antitoxin are that in cases of phthisis that are at all advanced it is of no value, and that in the one case of almost pure tuberculosis of larynx and upper lobe in which I used it, it was worse than useless, not having stayed the disease and having produced great physical suffering; that in the case of gland tuberculosis it has apparently done no harm and may yet be of value; that in all cases, with the exception of the last, the pain produced by the injection and the unpleasant after-results in the way of dermatitis and glandular swellings would almost, if indeed not entirely, prohibit its use.

The next series of cases to which I wish to call your attention gives brighter outlook as regards results from treatment.

In 1894 Dr. Victor C. Vaughan of Ann Arbor sent some of the early production of his yeast nuclein to Dr. Chas. G. Stockton of Buffalo, with whom I have the honor to be associated in one of our hospitals. Since that time Dr. Stockton and I have used nuclein on a number of cases of tuberculosis and other infectious diseases. I have yet failed to see a case in which it did not do good. I have seen many in which it has not effected a cure. I have seen some in which it has effected a cure. In all there has been at least temporary improvement.

Case 1.—The case of Miss C. I have already mentioned as showing marked improvement under the 1 per cent. nuclein. She had advanced as far as 3 c.c. at a dose, when, to my great regret, I changed to the tubercle antitoxin and she afterward refused treatment.

Case 2.—Mrs. W. F. H., age 57; nativity, United States. Nuclein. Tubercular family history; has coughed more or less for twelve or fifteen years. First came under observation in June, 1894. Suffering with gastric distress after eating; this has troubled her for the last eight years. Case is emaciated and has marked enteroptosis. The study of stomach contents shows slight diminution of hydrochloric acid, impaired motion and impaired absorption, large amount of lactic acid. Infiltration with some softening of upper lobe of left lung. Considerable cough and expectoration in the morning, slight at other time of day. Temperature ranges from 97 to 100 degrees, pulse 100 to 120, respiration 24 to 30. She was on cod liver oil, creosote and inhalation of menthol until June 15, 1895. Her weight fell during this year from 111 to 98 pounds. The diseased condition in the lungs also progressed so that when put upon nuclein,

June 11, 1895, her physical condition was poor, her appetite very small, sleep poor, gastric distress marked, occasional diarrhea, marked enemia and emaciation. There was infiltration of the upper right lobe and of the entire left lung with softening in the upper lobe. Weight 98 pounds.

August 2, 1895. She felt better and held her own in weight. A small cavity had developed in upper right lobe. The 1 per cent. nuclein was gradually increased in dose until by October, 1895, she was taking 6 c.c. hypodermically daily. She continued at that dose until May 1, 1897, then changed to 5 per cent. solution nuclein, begining with 1.5 c.c. and gradually increasing dose until May 20, 1897, when she was taking 4 c.c. She continued that dose. During these two years she has changed very little in her physical condition, except that the gastric indigestion has been to a great extent overcome. The sleep has improved, the cough has remained about the same, the strength of patient has not increased, the night sweats very seldom occur. Her pulmonary condition has varied, occasionally a little outburst of broncho-pneumonia occurring, but on the whole there has been a slight improvement. Since the beginning of the 5 per cent. nuclein this improvement has become marked.

May 20, 1897, physical examination showed that the cavity in upper right had disappeared though there remained some condensation of tissue there. There was small cavity in upper left with some infiltration about it. The cough diminished, the sputum was about the same in amount but less purulent in character, still containing tubercle bacilli. Temperature 97 to 99 degrees, pulse 100, respiration 22 to 26.

Case 3.—Elizabeth McD., age 42, American. Nuclein. First came under observation Nov. 11, 1895. History of pneumonia two years before and pleurisy one year before; since then loss of weight and strength, with cough and considerable expectoration. The records of this case, except the first and last physical examinations, have been lost. The first one, which was made Nov. 11, 1895, when nuclein was begun, showed slight infiltration in upper left, broncho-pneumonia areas in lower right, cavity surrounded by area of softening in upper right. Nuclein, 1 per cent. solution, was begun at 1 c.c. and gradually increased to 4 c.c., in February, 1896. She remained at this dose until she passed from under observation on Aug. 15, 1896, when her general condition was markedly improved; she had gained several pounds in weight, her appetite was good and bowels regular, she slept well, she coughed only occasionally and the last two examinations of sputum (which was very slight in amount) failed to show the presence of tubercle bacilli; physical examination showed that the signs of cavity and softening had entirely disappeared, leaving only the evidence of slight condensation in right apex: the signs of disease in lower right and left lung had entirely disappeared. Pulse 74, temperature 98 degrees, respiration 18.

This case I consider has recovered, though there remains slight condensation in upper right.

Case 4.—John D., age 21, nativity United States. Nuclein. This case came under observation Nov. 14, 1895, with a history of frequently occurring "colds" during the previous two years, and of a severe one in October, 1895, which has remained. Patient is losing in weight, sleeps poorly, has occasional night sweats, becomes slightly cyanosed upon exertion. There is considerable cough and expectoration. There is infiltration in upper right, infiltration and slight softening in upper left, bronchitis in lower left. Temperature 98 to 105 degrees, pulse 85 to 120, respiration 20 to 34. Injections of 1 per cent. nuclein begun Nov. 14, 1895. Weight 105 pounds.

December 17, 1895. During last month patient has shown no change in his general condition, except a slight improvement in appetite; the temperature 98 to 102.5 degrees, pulse 72 to 110, respiration 20 to 30. Cough and expectoration slightly increased. Area of infiltration and softening in left slightly increased.

January 16, 1896. Nuclein 4 c.c. Slight general improvement during past month, appetite and sleep improved, no night sweats, cough and sputum not materially changed. Temperature 98 to 101 degrees, pulse 80 to 120, respiration 20 to 30. Bronchitis has disappeared from lower left. Area of infiltration in upper left has diminished, but there is distinct, though small, cavity in upper left, but evidences of further softening are lacking.

February 17. During last month there has been very marked improvement in general health. Temperature 97 to 99.5 degrees, pulse 76 to 110, respiration 20 to 26, cough and sputum diminishing, cavity in left distinctly smaller, no softening about it. ished, no bronchitis, areas of infiltration in both lungs dimin-

March 17. Nuclein has reached 6 c.c. Patient's weight has increased to 122 pounds. Temperature 97 to 99 degrees, pulse 70 to 90, respiration 18 to 22.

April 17. Continued improvement in every respect. Good appetite, sleeps well, normal temperature, pulse and respiration. Improvement in left lung particularly marked. Infiltration in upper right still pronounced. Weight 130 pounds. Patient went to Colorado, but returned in late autumn feeling so well that he has neglected treatment all winter and spring.

May 20, 1897. Patient feeling very well, appetite good, no fever or sweats. Temperature 98 degrees, pulse 70 to 80, respiration 18. Evidences of disease have entirely disappeared from left lung, which seems in normal condition. Slight condensation of upper right with evidence of small cavity posteriorly at junction of suprascapular and interscapular regions. Cough much less, some days none, but sputum still contains the tubercle bacilli.

Case 5.—Christina S., age 17, German parentage. Nuclein. History of measles in early childhood, hip disease when 14 years of age, recurrence of disease at 16 years of age. For four months, during which she was under observation, before nuclein was begun, she felt badly, was losing in weight, appetite poor, bowels quite irregular, tending to constipation with occasional diarrhea.

Physical examination revealed bronchitis in right upper lobe. Infiltration and slight softening in left upper especially noticeable anteriorly in the infraclavicular and mammary regions, cough troublesome, expectoration about 150 c.c. in twenty-four hours. Pulse 80 to 110, temperature 97 to 102.5 degrees, respiration 25 to 35.

September 1, 1896. Nuclein begun. Weight 98 pounds.

September 13. During last two weeks there has been a slight change for better, both in the local signs and in the general symptoms. Pulse 70 to 96, temperature 97.5 to 98.5 degrees, respiration 24 to 26.

September 25. During the last ten days an acute pneumonic process has attacked upper left lobe, pulse reaching 120 in frequency, temperature 104 degrees, respiration 28 to 34.

After the subsidence of the pneumonia, the case made steady improvement in all respects; appetite good, bowels regular, color returning to face and patient enjoying a feeling of good health to which she had been a stranger for several years. Her pulse has ranged about 80, her temperature from 97 to 98.5 degrees, her respiration from 20 to 24.

May 10, 1897. Her right lung has cleared up entirely, the evidence of softening in the left lung has subsided and there remains only slight condensation in the upper lobe. The sputum has almost entirely gone, not more than 8 c.c. in twenty-four hours, containing only six or eight tubercle bacilli, in examination of eight slides, after precipitation of the sputum by means of the centrifuge. Patient has menstruated this week for the first time in a year.

Case 6.—David D., male, age 20, native of United States. Nuclein.

This case is the case of laryngeal and upper right lung tuberculosis that was given Paquin's antitoxin from January 29 to Feb. 26, 1897, and did so very poorly. Weight 123 pounds. Temperature 96 to 102.5 degrees, pulse 110 to 120, respiration 26 to 30. April 30 I began injections of 5 per cent. nuclein. At this time the patient's condition was one of anemia, anorexia, severe cough, frequent vomiting, poor sleep, great depression of spirits.

May 20, 1897.—During last month there has been gradual improvement in all respects; sleeps better, does not vomit so frequently, appetite better, acknowledges (for the first time in four months) that he is feeling better. Larynx shows slight improvement, signs of softening in right lung are disappearing, though condensation remains. Sputum somewhat less in quantity and a little more easily raised. Pulse ranges from 100 to 110, temperature 96 to 100 degrees, respiration 24 to 28.

May 22, 1897. Today noticed the first unpleasant effect from injection of nuclein. Immediately after the injection, which had been gradually increased to 4 c.c., patient said he felt badly, there was great difficulty in breathing and a feeling of nausea followed by a tremendous determination of blood to head and shoulders, giving them a dusky red hue. This lasted about five minutes and then gradually subsided. About one hour later it was followed by a chill which terminated in vomiting, and then the patient felt better but weak. There was left on the shoulders and upper chest a slight purplish mottling. Injection was omitted the following day. For the next four days injections were given, and twice a slight recurrence of the feeling was produced; on the fifth day the attack was similar to but more severe than the first. During the period before the flushing, patient became pulseless, face became pinched and drawn and without color, breathing shallow, infrequent and difficult. Death seemed imminent. The mottling which followed the flushing this time showed itself to be intradermal minute hemorrhages. Two days later I gave a smaller dose with a slight recurrence of the symptoms. The patient was evidently so terrified that the dread of the injection precluded the possible benefit and I have since begun giving the 5 per cent. solution by mouth, on an empty stomach, beginning with 2 c.c. and daily and gradually increasing to 4 c.c., t.i.d.

I should like to mention one other case that has been on treatment for two weeks only, but has made so great improvement as to surprise the patient, all her friends and myself:

Case 7.—Martha McD., aged 24, native of United States. bookkeeper. Nuclein. Came under my observation May 11. Father died of heart disease; mother of "tumor"; one sister of consumption.

Patient had measles and whooping cough when 8 to 10 years of age. Began menstruating when 14 years of age. When 18 years old had severe cough lasting two months; has coughed occasionally since. Three weeks ago caught a severe cold by change of clothing. Cough has constantly increased since that time. She has a tubercular aspect and weighs 112 pounds; pulse 104, soft and quick; temperature 99 degrees, respiration 24; she sleeps well and her digestive apparatus is in good condition; heart and blood vessels are sound; blood shows slight anemia. Nose is normal, but there is muco-pus in naso-pharynx; larynx normal; particles of broncho pneumonic infiltration throughout left lung, especially in upper lobe; sputum raised mostly in morning is muco-purulent in character, in chunks, contains tubercle bacilli, streptococci and diplococci lanceolati; amount raised in twenty-four hours 50 to 100 c.c. Treatment: Cod-liver oil and strychnin, t.i.d., and cough mixture of fl. ext. pruni virg., 1 c.c.; syr. scillæ comp., 1 c.c.; syr. lactucarii, 2 c.c.; every two to four hours. Nuclein, 5 per cent. sol., hypodermically; began with 0.30 gm. and increased dose gradually until she is now taking 2 c.c. daily.

May 27. She is feeling well, coughs only in the morning and thinks most of expectoration comes from naso-pharynx. Amount in twenty-four hours 15 c.c., is very tenacious, contains a few diplococci and a few streptococci, no tubercle bacilli. There are, however, still a few râles over upper lobe of left lung.

She has held her own in weight for the last two weeks, whereas before that she had been steadily losing.

Other cases that I have put upon nuclein have not been under observation long enough to justify any report. The following conclusions, however, I think are justified. Nuclein does no harm if injections are not too rapidly increased; the injections are not painful; one case recovered although there was a cavity in the right lung when treatment with nuclein was begun. The chronic case that has been on treatment for two years, receiving a hypodermic dose every day, bears witness to the value of the remedy. Signs of cavity have disappeared from one lung and become much less marked and and more limited in the other, the evidences of softening having also disappeared.

In one case beside the one that recovered, the bacilli have disappeared from sputum, which have become almost none. In another case I have no doubt that recovery might have been reported if the young man would stick to treatment, but he feels so well that he neglects himself, though the bacilli are still present and there remains signs of small cavity.

In closing this report I want to lay great stress upon the importance of properly conducted exercises in the treatment of pulmonary tuberculosis. Exercises designed to develop the chest muscles and increase the lung capacity; specific directions as to the character and amount of exercise and the time of day when the exercise should be taken are necessary. Whatever specific medication we may use, without exercise and fresh air our efforts will come to naught. The treatment of special symptoms deserves a few words:

Cough.—This symptom is generally best relieved by attention to the upper air passages, keeping them clean and free from secretion and by inhalations, mentha in some of its forms having been, in my experience, productive of the best results. The constant inhalation of essence of peppermint through a perforated zinc mask, as suggested by Carasso of Genoa, is especially valuable. When internal medication is needed to give further relief, the cough being irritating and the sputum difficult to raise, a combination of the fl. ext. pruni virg., syr. scillæ comp. aa 1 c.c., and syr. lactucarii q. s. ad 8 c.c. at a dose, given once in three to four hours has done best; chloroform water alone or combined with a little dilute hydrocyanic acid is very useful. Opium and its derivatives should be avoided entirely, excepting in advanced cases where they are the only remedies that give the patient any relief; of the various anodyne preparations, codeia and chlor-anodyne are the two that I have found most useful.

Dyspnea.—Not a very common symptom in phthisis, is sometimes very troublesome. For its relief, when not dependent upon the cardiac weakness, the fl. ext. quebracho I have found invaluable.

Pain in the chest is best relieved by strapping the chest or, if this fails, by hypodermic injection of morphin.

Hemoptysis.—Morphin hypodermically, rest in bed, dry cupping of chest, followed for several weeks by the internal use of the infusion of bugle-weed (*Lycopus Virginicus*).

Fever.—Best controlled by the nuclein administration. Sponging with alcohol and water is often of great value. Regular bathing should be a part of the routine treatment of every case.

Sweating.—This generally disappears during the treatment with nuclein. Sometimes, however, it requires special treatment. Atropin and aromatic sulphuric acid still remain at the head of the list of drugs useful in controlling this distressing symptom.

The *dyspeptic* symptoms require special study in each case and no general rule can be laid down for their treatment. Sometimes recourse to a diet of nothing but koumyss for two or three weeks will give the needed rest to the stomach and later allow a gradual return to a mixed diet. In all cases frequent examinations of the blood should be made in order to determine whether we are gaining on the anemia that is present to a greater or less degree in them all. Red bone marrow is the best agent to combat the anemia.

REMOTE EFFECTS OF BONE TRAUMA.

Read at the Third Annual Meeting of the American Academy of Railway Surgeons, held at Chicago, Ill., Sept. 23, 24 and 25, 1896.

BY D. S. FAIRCHILD, M.D.

SURGEON TO THE CHICAGO AND NORTHWESTERN RAILWAY,
CLINTON, IOWA.

Some experiences during the past few years has suggested the subject of this paper, and I have in consequence examined a considerable range of medical literature for the purpose of obtaining data upon which to base certain propositions. The result is somewhat disappointing for the reason that writers, even those standing highest as authorities, have written but little in reference to the remote consequences of bone injury, especially in relation to such cases as may become the subject of controversy. Exception must be made of the writings of those who before the discovery of the special cause of tuberculosis regarded certain classes of joint disease and certain cases of osteomyelitis as the result of injury more or less remote, recognized or assumed

The effects of injuries upon the future condition of bone tissue are so varying in their nature that it would be quite impossible to predicate the future possibilities in any case of trauma in an empiric manner based upon experience alone, but rather, in the first place, on well-known pathologic facts. The apparent relation of cause and effect in medicine are, as is well known, so often misleading that a most critical application of facts, derived from a close study of pathology, becomes necessary to protect the surgeon from falling into serious error. So many writers on medical, as well as on other subjects, have fallen into the habit of loose and indefinite statement, that it is not difficult to find that the highest authority may be used in the support of propositions, often no doubt, quite in discordance with the author's real views.

It is true that unusual difficulties lie in the way of certainty in medicine from the fact of the complex nature of the subject and of the unforseen accidents which may arise to complicate the course of events, but much of this may be avoided by the employment of critical methods of study. The primary consideration in the study of the subject of this paper must be the influence of injuries in producing bone inflammation.

It is generally agreed that contusions of bone will produce swelling of the periosteum from extravasation and if the injury is sufficient or of such a character as to influence the bone an osteoplastic process will follow. It may generally be expected that resolution will take place in a short time, and that the periosteum and bone will be restored to to their former condition. If, however, this does not take place other results will follow, which it is the object of this paper to consider, and if we can reach an understanding of what may be expected from the standpoint of pathology and from the most reliable practical observations, we may be able to answer certain questions and come to conclusions which will be just and proper.

Leaving out of consideration for the present moment the results of infection, we will consider the effects of the osteoplastic process when resolution does not take place. I think it proper to stop long enough at this point to say that chronic irritation or inflammation of bone can not continue for an indefinite period of time without certain organic changes taking place. Assuming an injury to be the cause of an inflammation or an irritation of a more or less persistent character, we have as a result a proliferation of cells.

The density of bone tissue is such as to interfere with this multiplication of cells without the occurrence of a coincident absorption of bone substance, hence the bone changes in condition. The vascular structure of bone periosteum and medulla are involved, becoming more vascular and an exudation takes place underneath the periosteum into the medulla and into the enlarged Haversian canals, or in spongy bone into the trabecular structure. As the embryonic cells increase in number the osseous lamella becomes softened and absorbed and the lacunæ become larger, and these with the enlarged Haversian canals become filled with granulation tissue together with multinuclear cells, osteoclasts, which are believed to aid in the absorption of bone.

This form of inflammation of bone, known as rarefying ostitis, is attended with the formation of new bone beneath the periosteum and in the medulla, hence two processes are observed: 1, new embryonic cells and enlargement of lacunar spaces and Haversian canals; 2, the conversion of the new elements into bone.

Therefore the two processes of rarefying and formative ostitis occurring together give rise to conditions which will vary according to the predominance of the one or the other. If the irritation continues, resolution, of course, does not take place and disease becomes progressive, involving well determined pathologic changes, be they of the character of rarefying ostitis or osteo-sclerosis. If the disease is chronic or slow in development the rarefying process continues until an abnormal degree of sponginess is reached, whereby the bone becomes larger, lighter and lessened in its power of resistance and fracture easily occurs. Section of a bone which has undergone this change will show the numerous spaces, the enlarged Haversian canals and medulla or the more fragile condition of the trabecula. The extent of these abnormal appearances will be determined by the degree of inflammation present and the advancement it has made.

If, instead of the continuance of the rarefying process, the bone granulation tissue becomes organized and new bone is formed, the spaces become slowly filled, the medulla is encroached upon and the bone becomes changed in character; it becomes harder and denser. The continuance of the bone formation process indefinitely must result in an interference with the vascular supply by compression of the blood vessels and an ultimate interference with the nutrition of the bone, leading finally to necrosis of greater or lesser areas. If, however, the disease becomes arrested at a point short of a serious interference with nutrition, the condition of osteo-sclerosis may remain permanent. The lesson, then, to be derived from a consideration of the pathologic changes in chronic inflammation in bone, teaches that this condition can not continue indefinitely without giving rise to well marked internal and also external changes, which may be readily recognized if the bone is situated superficially so as to place it within easy reach. No doubt slight degrees of pathologic changes may take place without objective signs which can be discovered by ordinary surface examination.

It appears from a considerable personal observation among railway and mill employes that the organic changes in bone resulting from chronic inflammation rarely terminates in complete resolution, a degree of permanent thickening remains, which, however, gives rise to no troublesome symptoms or disability, unless the thickening is in the immediate neighborhood of a joint. There may be no constant relation between the severity of the subjective symptoms, the extent of pathologic changes and the objective signs, but it is fair to presume that if symptoms of disease persist without abatement, more or less active changes are really taking place with the results already indicated.

The foregoing relates to cases which escape the influence of microbic action, either septic or tubercular. In predicting the future results of bone inflammation we have always in mind the possibility of infection. In general terms it may be said that the more abundant the granulation tissue, the more active the suppurative process in the event of pus infection, a condition most often met with in inflammation of spongy bone, or in the trabecular structure of long bones near the articular extremities. A traumatic osteomyelitis with pus infection, occurring early or late, means a pathologic condition, manifested by evidences of a positive character, showing very soon the serious nature of the lesion; the more or less rapid approach of pus to the surface, redness and inflammation of the soft parts and final discharge, and the formation of sinuses communicating with carious or necrotic bone. In the case of rarefying ostitis of denser bone, the granulation tissue filling the enlarged spaces may become infected and the lesser formation of pus, and the more localized process may give rise to a small abscess, chronic in character and occasion less marked symptoms, but in the search for the cause of the symptoms the objective evidence will be unmistakable.

Tubercular infection of the actively granulating tissue will be marked very soon by an accession in the symptoms and a more decided progress of the disease, the early formation of sinuses consequent on the development of tuberculous pus, and if double infection from the invasion of the true pus microbe happens, the added constitutional symptoms of sepsis will follow.

There can be no doubt according to the best authorities that an ostitis of traumatic origin, even if resolution has taken place, at least to the extent of subsidence of all active inflammatory processes, may become the focus of a tubercular development, by serving as a point of least resistance. But can we say that this local predisposition to tubercular infection is permanent, *i. e.*, that after all inflammation has subsided and the structural changes have been followed by a restoration in the nutritive balance, can we say that the thickened bone, or the bone that has been subject to an inflammation, is still exposed to the special danger of a tubercular disease. The best evidence is to the effect that when the nutrition of the bone has been restored the *locus minoris resistentiæ* ceases to exist. The time for infection is when the nutrition is impaired by the products of inflammation, or when the products are in that special condition which invites the cultivation of the bacillus tuberculosis. It may be difficult to determine when the bone has become restored to that condition of normal resistance, but to my mind the appearance of a tuberculous process long after all evidence, save the thickening, of the inflammation has disappeared, is not sufficient evidence of the causative relation of the inflammation itself.

It is generally admitted that an injury to a bone, particularly to the cancellous structure in which trabeculæ are broken or in which a minute hemorrhage occurs may be the foundation of a tuberculous inflammation having its exact seat either in the new cells formed incident to repair, or in the hemorrhagic focus.

In the examination of a case of bone inflammation, even when resolution is apparently going on favorably, we can not avoid the apprehension that a tuberculous process may develop at any time, and in the light of this fact our opinion must be guarded, for the otherwise reasonable expectation of a recovery may not be realized. If it is true, as it is generally accepted, that an injured or chronically inflamed bone is subject to tubercular infection, for how long a time and under what circumstances may the above conditions serve as etiologic factors in the production of the disease? Much loose generalizing has been indulged in on this point and efforts have been made to show that a slight injury to a bone may give rise to a locus *minoris resistentiæ* which will especially predispose to the disease for an indefinite time. That is, if a bone becomes injured and all symptoms of such injury subside, yet after months, or even years, tuberculous process develops. Therefore, it is said that the injury is the remote cause. It may also be assumed in a given case of injury that even if apparent recovery takes place the claimant is exposed for an indefinite period to the rise of a dangerous disease as the logical sequence of the injury.

I am not advised that any modern writer of eminence holds to this view, but it is a fact that opinions of this character are entertained by members of the profession. Senn regards bone tuberculosis as the result of trauma under any circumstances as rare, and Cheyne, while believing in the etiologic influence of injuries in producing bone tuberculosis, cites only a few cases in which there was satisfactory evidence to his mind of the causal relation, and in all these cases the tuberculosis followed immediately without any apparent recovery from the injury itself, and the same is true of all other cases recently recorded. Referring to a previous statement in this paper, I contend that the circumstances under which infection must occur, if at all, is when the local resistance in the bone is impaired by the injury; or in the presence of a minute hemorrhage; or in the presence of granulation tissue as the result of a mild inflammation or repair; and the limits of infection must not extend beyond the restoration of the injured bone to its normal condition and that the evidence of such restoration must be the disappearance of objective symptoms in bones subject to easy physical examination.

The origin of a true bone tumor from a metaplastic process is no longer entertained. The formation of an exostosis or a localized or diffused hypertrophy from the reparative process in a bone following an injury may occur, but the fact is so plainly indicated by the physical condition of the bone that it can not fail of recognition and the continuity of symptoms subjective and objective with the development of the bone enlargement will indicate the causative relation, however slow the process may be. In the process itself we recognize the histogenetic changes already considered, viz.: Hyperemia, exudation and proliferation of cells from the deeper layer of periosteum and the conversion of the osteoplastic elements into bone.

The development of sarcoma from bone trauma is altogether possible, especially in persons predisposed through heredity. This is occasionally seen to occur in the immature callus after fracture.

In irritation following trauma newly formed embryonic cells may form the matrix for a sarcomatous development through failure to undergo transformation into tissue of a higher or more resistant physiologic type. That hereditary predisposition is not absolutely necessary in the development of a sarcoma matrix, although it must be assumed in the present state of knowledge of the histogenesis of tumors that a preëxisting matrix of embryonic tissue was present to be lighted into activity under favorable conditions, was shown in a case which came under my care some eight years ago. A man received an injury to the middle of the right humerus, not sufficient to produce a fracture; this was followed by a moderate irritation in the bone accompanied by sufficient pain or uneasiness to attract his attention when not otherwise engaged; in a few months he observed that the bone was increasing in size. The enlargement gradually increased during a period of two or three years, until it became difficult to pull over it a coat sleeve of ordinary size; finally the bone was fractured by ordinary muscular effort. The bone appeared to unite but the condition became so troublesome that he consulted me. The malignant nature of the disease was so apparent that I had no hesitation in declaring it to be a sarcoma of the bone, and advised amputation at the shoulder joint. The proposition was promptly accepted and the arm removed. A microscopic study showed the disease to be a sarcoma of the myeloid type; the growth beginning in the medulla and finally leading to the absorption of bone and extending to the contiguous soft parts. There has never been any return of the disease. The sequence of events satisfied me that trauma was an important factor in the etiology of the disease.

The practical propositions involved in this paper are based on inflammation or irritation in bone following injury and the sequel resulting therefrom.

1. Resolution, including a complete restoration of the bone to its normal condition, occurs in the vast majority of cases.

2. Resulting in rarefying ostitis. Condensing ostitis, or a combined rarefying and condensing ostitis, which may remain as a more or less permanent condition; if slight in degree giving rise to no well marked subjective or objective signs after the process becomes arrested.

3. If the process continues for a period beyond a few months, well marked and unmistakable changes in the physical condition and appearance of the bone will become manifest.

4. A persistent acute or chronic osteomyelitis will also give rise to unmistakable physical changes in the bone.

5. A persistent chronic osteo-periostitis will give rise to thickening of both periosteum and bone of a character that will be readily recognized if the bone is so situated as to admit of easy surface examination.

6. If the products of inflammation in cases of rarefying ostitis or in osteomyelitis become infected with pus-forming microbes, the suppurative process will become plainly evident, except in cases in which the process is very limited, giving rise to a small abscess in the bone which may be indicated only by subjective symptoms.

7. The injury and irritation following may establish a locus minoris resistentiæ which may become the seat of tubercular infection with certain definite results. The length of time after a trauma, during which this influence may exist, can not be definitely determined, but it may be assumed in the light of critical practical experience and pathologic research that the special predisposition will cease to exist as soon as the effused blood is absorbed, and the protoplasmic elements—the products of irritation or inflammation—have been resolved into new bone or have undergone degeneration and absorption, *i. e.*, as soon as the normal nutrition balance is restored. I do not believe there is any scientific evidence or any practical facts that will bear criticism, which will support the assumption that the locus minoris resistentiæ may continue for months or years after all signs of the injury and its immediate results have disappeared.

8. There is no evidence to show that a carcinoma or

sarcoma may develop as the result of an injury after the immature bone elements have become transformed into tissue of a normal resisting physiologic type.

DISCUSSION.

Dr. Reed, Columbus—The subject of "Remote Effects of Bone Trauma" is of interest to every surgeon, and especially to the railroad surgeon; the repairing of bone, the possibility of disease and the changes that are wrought, are all points which may interest the surgeon and interest the company—especially if the patient has occasion to call on the company for damages. The subject has been very ably handled by the Doctor; he has reviewed in brief and concise form cases relative to the repairing of bone, and the changes which take place in the anatomy, in an admirable way; at the same time there are some points which the Doctor did not touch upon, and which might be of interest to us in this connection. I have no doubt you have all had occasion to observe in your practice cases in which you had taken the best care, and in which you had put on the ordinary splint, kept the bone in proper position and to all appearances in apposition, kept him quiet the ordinary amount of time, the patient had got well; and yet after all this the patient after he was given his liberty would go out and come back to you probably in one or two years afterward with a deformed limb. Now the question comes up, Is that the fault of the surgeon or is the company in any way liable? I have in mind two cases of this kind in which the patients had a fracture of the femur, an ordinary fracture in one case and an oblique in the other; in each the patient was cared for by a competent surgeon, and was dismissed with little or no deformity, or very little shortening, and yet in each ease after the patient had gone out about his business his limb became deformed. Now we have there a case of imperfect repair. We have no doubt had in the first place a perfect union, the intervening space filled, new bone tissue formed, that is, the bone cells had bridged across the chasm, but they were not properly supplied with lime salts so as to harden them, and the result is that instead of that new bone becoming solid it was still elastic, of a cartilaginous character and we, in one case, had the bone not becoming actually displaced but giving away and causing a bow leg. In the other case the union was solid and the weight of the man on the limb gradually forced the bones past each other, not because they were not united, but because there was not sufficient bone salt to make the new bone hard. Those are points I do not think the railway company or any other company are responsible for. I think we ought to discriminate between cases in which deformity followed a union and the case where the surgeon did not properly adjust the bones from the case where the man does not have sufficient vitality to repair the bone properly, or to furnish the lime salt after the new bone was formed. Again, in reference to sarcoma, the Doctor speaks of what I think it is well to remember, that in the case of sarcoma we can not have a sarcoma following traumatism—and I think Dr. Senn has gone into that in his last work very thoroughly—unless there is is a prenatal or post-natal embryonic cell condition; if there is a prenatal or post natal disposition then a traumatic trouble may cause sarcoma, but this must exist prior to the injury and is liable to be the result of previous condition because we know sarcoma does occur without there being a trumatism at all.

In reference to tuberculosis, I recall a case that came to my notice in the hospital a year and a half ago, in which there was a marked case of tuberculosis; a gentleman had pulmonary tuberculosis, which was confirmed not only by expert diagnostitians, but by microscopic examination of expectoration, and in this case the person was emaciated and to all appearances he would die from tuberculosis before he had time to repair bone. It was a railroad accident and he was caught between the cars when the accident occurred, and there were seven distinct fractures distributed between ankles and knees. I observed in this case one fracture repaired at a time—one fracture and then on the same limb another fracture and so on; it went the round, finishing one limb before repairing the other; it was a beautiful case, and notwithstanding he was suffering from tuberculosis, coughing and expectorating profusely, the repair processes went right along just as promptly, so far as any one fracture was concerned, as if tuberculosis did not exist at all. Now the point is this: If tuberculosis is liable to come as the result of injury why would it not occur where the man was suffering from tuberculosis and the whole system run down from disease and in an ill condition to take on reparative processes at all, but we do not have it occurring in any other part of the system excepting the lung. I simply bring these cases up to emphasize what the Doctor has said in his paper, that I do not believe an injury, a traumatism, is conducive to the development of tuberculosis or sarcoma in and of itself, that it requires a condition that is entirely separate from the traumatism to induce it.

Dr. E. M. Dooley, Buffalo—Dr. Reed's remarks in reference to remote effects of bone trauma in case of fractures recall to my mind an interesting case that occurred in Buffalo about three years ago in which the case was a fracture of the tibia about the middle, and a classmate of mine attended him. He had a perfect result and a rigid union and the patient was able to use his limb. But a year afterward at the seat of fracture the callus softened and he had in reality a case of nonunion. The case was interesting because the surgeon was sued for malpractice. Now it was a case of the fault of the patient and not the surgeon, yet, although the surgeon won his suit, it put him to a great deal of expense, both in time and money. And I think these remarks in reference to the possibility of fracture, after it has firmly united to all appearances, softening a year or year and a half later, worthy of emphasis.

Dr. C. K. Cole, Helena—*Apropos* of what has just been said, I wish to refer to a case which occurred about two years ago in the practice of one of my neighbors, and which illustrates one of the phases of the subject touched upon in this paper. A man while riding on horseback was rubbed against a tree and the humerus was broken near the head, which was dislocated. The accident occurred in a remote region and a doctor was not consulted until, I think, four days subsequent, when the man received proper attention. The head of the bone was reduced, the fracture was restored. The patient then and for some weeks following complained of pain, increasing constantly. He consulted a prominent surgeon in San Francisco, who, after making a cursory examination said some things to the patient which reflected upon the doctor who had charge of the case, and these reflections suggested to the patient a suit for malpractice. But before bringing the suit, Dr. Senn of this city was consulted, and Dr. Senn discovered—I think this was some four months after the accident—an osteo sarcoma. Amputation was resorted to, injections were practiced, and the patient remained in St. Joseph's Hospital for some weeks; he returned home and again came to Chicago and was again treated, in the meantime having instituted legal proceedings against the doctor; and he died here in Chicago from a bona fide sarcomatous growth. The reason for calling attention to this case is that it is pertinent to one phase of the subject discussed in the paper and that is a phase of the subject that is not well understood. The fact that a traumatism may precipitate this growth, as Dr. Reed has well said, so far as our knowledge goes there is a preexisting condition, but an injury of this kind does precipitate a growth of this character. The medico-legal aspect is interesting to us as railway surgeons, because unless this is well understood we, and the companies we represent, are liable to be sued for malpractice in cases in which we are not at fault.

The President—I remember a case where a blow was received on the clavicle and on the skull, and sarcoma developed in both places, at the two contusions.

Dr. Galbraith, Omaha—I don't believe we will have a more important paper before this Association than the one just read. While we have so far confined ourselves entirely to pathology of bone trauma, bone inflammation and the products of bone inflammation, I think it would be well for us to give the treatment of these conditions, these lesions, some consideration, more especially as to that part of the bone which enters into the formation of the joints, inasmuch as the treatment in my belief, varies as regards the location of the bone, more especially does that apply to traumatic osteomyelitis. At various times I noted that the Doctor spoke of resolution following, as I understood, simple osteomyelitis. This may occur, but as regards the syphilitic, I do not think it possible; I believe osteomyelitis attacks this portion of the bone. More especially is this subject one, or should be one, of the most serious considerations that is presented to us of a surgical character, and my results in almost every case I can recall to mind now have been a necessitated amputation.

Dr. Ward, Conneaut—I happened to be unfortunate enough to witness a case in which a man 50 years of age had a very large osteo-sarcoma develop after the fracture of a clavicle. From its magnitude, before attention was called to it, any operative procedure was interdicted, but in connection with it there developed a very friable condition of the osseous structure generally, and from the simple act of turning in bed, or something of that kind, fractures of one or more of the limbs occurred, and death finally ended the scene. This man was supposed to be healthy and in good condition until he met with the accident leading to the fracture of the clavicle, but from that time on there was a general decline, with the development of the condition specified filling all the space. It was a very large growth and a degeneration of the bone structure generally.

There must have been a preëxisting constitutional condition, but undoubtedly, in that case the fracture was the exciting cause or the developing cause of the trouble that immediately followed.

Dr. Reed—Permit me just to make one statement in rebuttal, as they would say in court, to the remark made by our distinguished President; he spoke of sarcoma following contusion on the head and on the clavicle. I simply want to say, not less than eight weeks ago, I made an an exploratory incision into the abdomen for the purpose of diagnosis, and there I found a sarcoma of the liver and the left kidney, the lower portion of the right lobe of the liver and the right kidney, and both distinct, as far as any anatomic connection was concerned.

Dr. Eggleston, Seattle—A young man about 28 years of age, inmate of a penitentiary, while working in a brickyard received a blow on the right side of the skull from a piece of brick thrown by one of the other inmates, and a few months later a tumor developed at the point of injury, which was at first attempted to be removed by the surgeon of the penitentiary; he had to stop the operation on account of excessive hemorrhage; I believe that he attempted to do it under cocain without an anesthetic; a few months later he gave an anesthetic and removed the clot, scraping off the bits of bone; it healed nicely, but a few months later it developed again, and when it came back, a year ago last June, I observed there was a tumor on that side of the skull as large as a goose egg; I pronounced it a sarcoma. I happened to have at that time some of Dr. Colles' culture of the erysipelas and commenced the use of that by injecting it in the tumor and pushed it to the extent that I almost killed the patient, but it had no result on the growth. It went on and a few months later another tumor developed on the opposite side of the skull about the juncture of the parietal with the frontal bone, and in a short time he developed paralysis on the left side from pressure on the right side, and died. A postmortem was had; the tumor went down through the skull and pressed on the brain as large as a goose egg and there was a deposit of two or three pounds of the sarcomatous growth in the left cavity. A sarcoma resulted from contusion of the bone in this instance.

Dr. Baldwin, Salt Lake City—A man running from a policeman jumped on a shed and broke his thigh. I happened to be one of two to dress the wound. After the first, there was union there but not a bony union. Afterward he fell into the hands of Dr. Cole and that portion was excised and the bone wired, but never got a union; the result was that they finally amputated it. I have in mind another case that possibly shows the result of very remote traumatism: A young boy about 13 years old was playing with a dynamite cap which exploded and struck him on the head and it was thought only the outer table of the skull was fractured. But it went on for something like four years, when I first saw him and he began to suffer with severe pain, I do not know how long, but two or three years after the injury; and it kept up so long that it was said that something was necessary to be done. At the same time, I think about the time the pain began, he began to have indigestion—he could not eat anything or keep anything on his stomach. Dr. Cole and myself trephined and removed a portion of the bone and afterward he was relieved of the pain and materially relieved of the indigestion or the stomach trouble. Now what connection that could have with the stomach I do not know, but certain it was he was relieved considerably.

Dr. Fairchild—The object of this paper was to call the attention more particularly to sequelæ which might appear as the remote effect after apparent repair had taken place. It sometimes happens we have a patient alleging pain and difficulty in a bone like the tibia, for instance, which is exposed to easy examination and it is alleged this is due to inflammation in that bone. On examination we find nothing whatever, no thickening of any kind in any direction. Now, the question would be whether or not we could have an inflammation persisting in a bone for a long period of time, say one or two years, without any marked signs being manifest. That was one of the propositions in the paper, whether we could have a bone inflammation continue without giving rise to physical signs. I have one or two cases of that kind, a patient that hobbled around on crutches and having litigations over it, and yet a physical examination showed no sign whatever of a physical character. Then further along after the injury we might expect tuberculous disease to develop. Now in case of fracture I believe it is true that tuberculosis does not generally occur, because reaction is so active that tuberculosis is not ready to develop, that it develops in slighter injuries. Now, in slighter injuries can we say a tubercular process is liable to develop in that bone. Suppose for instance a patient received injury and it apparently healed, no sepsis discovered; yet eighteen months or an almost two years, say, lacking a day, the patient has a tubercular process develop. Now a suit is commenced, instituted on the ground of tuberculosis as the result of the injury, and yet there was no sepsis for many months. These were points on which I was anxious to get some information. Again, in case of injury to a bone which has healed, repair has taken place, and yet a year and a half after that a sarcoma develops at the seat of injury. Sometimes we are able to determine that all the nutritive balances have been established, the cells have reached maturity, perfect physiologic poise has been reached, and yet a sarcoma develops. Can we say it was the injury which caused that sarcoma, or that it resulted from the injury received months before? Those were the points I desired to bring up, and in looking up the authorities I have had difficulty to find any authority specific enough on this subject as to enable one to believe or to form an opinion as to a consensus of medical opinion. We hear in litigation, what changes will occur in bone tuberculosis, and I have attempted to say that when the nutritive balance was restored in the bone then the danger from tuberculosis was ended, and the question would be to determine when the nutritive balance was restored, whether the repair process has occurred and cells restored to maturity. We do not believe the cell that has reached a state of maturity will become degenerate, so that in bone when the bone has become restored to a normal condition tuberculosis does not occur as the result of injury. We pretend to say that in injury to the bone if the cells become restored to physical maturity, if sarcoma develops, it is not the result of the injury. It was not intended to discuss the question of reabsorption of the callus in case of fracture, although as the discussion has gone in that direction I will mention a case, a compound fracture of the bones of the forearm; the part healed without union; the bones were resected and wired, and union began. Then it was noticed after a while that an additional joint existed, that is the callus had become absorbed. A friend of mine in Washington was operated on in the same way, and I had a letter from the doctor in which he stated he had excellent results. I saw the case six months later and the additional joint was there. But this branch of the subject I did not take up, but simply the matter of the future possibilities in the examination of an individual case; and in examining a case in which there is a claim made, can we say this condition has any bearing upon the injury which the person alleges to have received?

SOCIETY PROCEEDINGS.

Medical Society of the State of Pennsylvania.

Minutes of the Forty-seventh Annual Session.

(Concluded from page 32.)

The next paper was by Dr. E. H. James of Harrisburg, on

PLEURITIS.

Until recent years, the exposure to wet and cold was supposed to be the cause of pleurisy. Medical text-books of less than a quarter of a century ago spoke of it as occurring idiopathically, or to quote Flint, "in the large proportion of cases it is spontaneous, that is, it proceeds from some unknown cause." The discovery of the tubercle bacillus by Koch in 1881 revolutionized our knowledge of the subject. We know now that the majority of pleurisies are caused by tubercular infection. It has been found that the tubercle bacillus has the property of exciting a fibrinous or a suppurative inflammation not necessarily specific in character. The infection of pleurisy like that of phthisis is not a simple but a mixed one. Some of the micro-organisms are more destructive in character than the tubercle bacilli.

A certain proportion of pleurisies are undoubtedly of rheumatic origin. The infectious matter which will excite a rheumatic polyarthritis in one individual may in another cause pleurisy or inflammation, in another serous membrane.

Treatment: In the acute stage, acetate of potassa, 15 grains, tr. aconite R. 2 drops; sulph. codeiæ gr. $^1/_8$; spirits of mindererus 2 drams. This mixture to be given every three hours. Dry heat externally. When of the rheumatic type add 10 grains of salicylate of sodium to the mixture given above. To get rid of an effusion of serum, withhold liquids as much as possible and give saline purgatives and diuretics; the blood being thus deprived of its watery elements will frequently take up that from the pleura. If it does not do so the aspirator should be used and from ten to twelve ounces of liquid withdrawn, the remainder will usually promptly disappear. The character of the fluid in the pleural sac may be easily determined by withdrawing some with a hypodermic syringe. When pus is found neither the aspirator nor trocar and canula should be used, but a free incision should be made in the seventh or eighth intercostal space on a line with the posterior axillary fold; the pus and fibrinous clots can thus be thoroughly evacuated, after which a drainage tube guarded with a safety pin should be introduced and a dressing of sterile gauze and cotton applied. The tube may be shortened from time to time and when the discharge is thin or serous may be withdrawn. The initial operation as well as all subsequent dressings must be done with strict aseptic methods, the danger of acute infection is great. It is necessary to excise a portion of rib when drainage can not be properly secured by thoracotomy. This allows thorough exploration, pockets of pus can be broken up, drainage will be perfect. Irrigation of the pleural sac I believe is harmful, it irritates, delicate adhesions are broken up.

In the pre-antiseptic era according to statistics 87½ per cent. of empyemas died. Today we expect over 90 per cent. to recover. Of six cases of empyema which I treated recently all recovered. In one of these a portion of the seventh rib was excised, the others treated by thoracotomy and drainage.

A resolution was adopted by which each member was earnestly requested to write to his members of the Legislature urging the passage of the Act now before them relative to malpractice suits.

Dr. W. M. **Robertson** of Warren presented a paper on

A COMMON CAUSE OF LOOSE BODIES IN THE KNEE JOINT.

An authority says that "In joints that have been free of disease loose bodies are invariably the result of a trauma." It is my intention to direct your minds to the more common lesion of the knee joint produced by trauma according to the teachings of Arbuthnot Lane of Guy's Hospital, London.

Injuries to the knee usually occur when it is flexed. As in all hinge joints the articular surfaces of the knee are best protected when in a position of extension. In flexion the articular surface of the tibia covered by the interarticular cartilages glides backward on the femur, exposing the articular surfaces of the condyles of the femur. During flexion the patella falls more and more into the intercondyloid notch of the femur and forms a great protection, but you will observe that the outer condyle is favored much more than the inner one. It is a great defense to the joint from injuries inflicted in front and distributes the weight when in the kneeling posture.

In falling forward the thighs are usually abducted in such manner that the exposed and unprotected articular surface of the inner condyle sustains the force of the fall and receives the trauma from which the loose bodies originate later on.

It has been supposed that these bodies came from the separation of portions of synovial fringes and injuries to the semilunar cartilages and without doubt such is the case many times, but in the majority of cases Arbuthnot Lane has demonstrated that the more common origin of loose bodies is the dry necrosis and separation of a portion of the articular fibro-cartilage of the inner condyle injured by direct violence, such as is sustained by a fall forward. In these cases the blow suffered by the articular surface is sufficient to devitalize the area.

The nutritive processes are stopped and after a time separation of the cartilage occurs and becomes the loose or floating body in the joint. This may produce the history of locking and pain, or it may give rise to simple chronic synovitis, which may in time present every appearance of rheumatoid arthritis or of tubercular disease.

A number of cases might be cited in which Mr. Lane exposed the inner condyle to view showing the area from which the cartilage had separated and then after careful search enough of cartilage found in the joint to exactly correspond to the space left after its separation.

The practical point is to recognize these cases and lose no time in operating. In a number of cases I saw Mr. Lane pare off the edge of partially dislocated semi-lunar cartilage of the knee.

Dr. **Eugene Wasdin**, Pittsburg, read a paper on

PATHOLOGY OF INFLUENZA.

Laboratory observation has alone resulted in any service here. The organism of causation has been demonstrated by Pfeiffer and Canon. It is difficult of cultivation. This disease is of great importance. It increases largely the death rate from pneumonia. He sketched its complications at some length, demonstrated the gravity of the disease, even when uncomplicated. Unfortunately, the nomenclature is much confused. General symptoms of catarrh of the stomach and small intestine are frequent. After the thoracic condition is pronounced, attention is called to the distension of the abdomen. There is no pain, but a sense of fulness, diaphragm is displaced, the weakened heart much embarrassed; all this depends upon the toxic influence of the sympathetic nerve supply. In the lungs the elastic tissue being highly organized, impairment of this tissue is followed by loss of proper action of the capillaries.

Dr. J. M. **Douthett** of Pittsburg read a paper on

CLIMATE IN CONSUMPTION.

He alluded to the want of attention to the physiologic effect of climate. We need reliable statistics on the climate of these places so much lauded for consumptives. Each vaunts its own and attacks the others. Few can go away, not having the means to travel. The most desirable conditions are: As much altitude as the patient can stand; as little humidity as possible; moderate temperature devoid of cold. High altitude increases the red blood corpuscles, with an increase of the hemoglobin, increase of lung expansion. In elevated arid regions, decay is slow, and indeed under favorable conditions does not occur, because of dryness, air purity, freedom from organic dust and germs, large amount of ozone present, etc. A dry climate is very important; next an even temperature. On the whole, the central plateau of Mexico presents the best climate for the tuberculous, combining desired altitude, low humidity, even in the winter months, and in the mountains one may have very pleasant summer weather. Hotel accommodations are very poor, the chance for employment is moderately good if one knows the Spanish language. El Paso and Las Cruces are the best all-round places in the United States. In western Texas are numerous places where one might obtain employment at a ranch or in the mines. Colorado has too severe winters, summer is the best time there. For those who have heart complications, Florida and Southern California are the best. A residence of several years is needed for a cure, hence it is necessary to find employment so as to get interested in the place. Sanatoriums are of advantage to a certain class; all should be encouraged to obtain out-door employment, to get the benefit of the sun and fresh air.

Dr. **Evan O'Neill Kane** of Kane read a paper on

WHY THE TOBACCO HABIT IS PECULIARLY REPREHENSIBLE IN AND DETRIMENTAL TO PHYSICIANS.

His purpose was to draw the attention of the profession to the injury which they do both to themselves and to their patients by this indulgence. In order to prove the truth of this statement, it is pointed out that no delicate patient can tolerate the odor of tobacco which the attending physician frequently intrudes upon them. Stress is laid upon the fact that all special senses are to a more or less serious extent dulled by using tobacco, the power to diagnose disease being thus greatly curtailed. Having passed briefly in review the manner in which each of the special senses suffers, the paper closes with the claim that even the will power becomes weakened in those who are addicted to the tobacco habit.

Singular to say, this paper was received with a round of applause from all present, as also were the remarks of Dr. A. B. Brumbaugh of Huntingdon, who fully accorded with Dr. Kane and arraigned the members for the indulgence so freely on the occasion of the reception the evening before, where every lady was compelled to pass through a crowd of smokers in order to reach the parlor where the reception was being held.

THE FAUCIAL TONSIL AS AN AGENT IN SYSTEMIC INFECTION

was discussed by Dr. G. B. **Sweeny** of Pittsburg. The faucial tonsil occupies a humble position. As an agent for the secretion of fluid to aid deglutition, it is no more active than the surrounding mucous membrane. It is only when it becomes the seat of disease that it demands attention. While in a state of inflammation it frequently affects the entire economy. It is a most readily accessible point of attack in infections; however mild the process, the tonsil becomes a hot-bed for infection, and readily distributes morbid products to adjacent and remote organs. Interfering when enlarged with respiration, it produces the "mouth breathers." Hence improperly filtered, moistened and warmed air is hastily conveyed to the lungs, oxygenation is prevented; we see then the dull, listless eye, impaired mentality, the pallid complexion, contracted chest, anemic and wasted muscular organism. The tonsil is a vulnerable point of attack for diphtheria, and often a culture medium for propagation of germs which would otherwise perish. We are now able to establish almost beyond doubt the infectious nature of rheumatism. We can not fail to observe the analogy in the systemic symptoms of follicular tonsillitis and acute rheumatism. Though we have not yet been able to isolate a germ for rheumatism, yet in this disease we find in the blood streptococci which characterize follicular tonsillitis, and are found in the tonsil when affected by that disease. Tuberculosis shows us the glandular system largely affected. Here we may regard the tonsil as mainly if not wholly the source of infection. So with typhoid and malarial fevers due to a specific bacillus, and as drinking water plays a conspicuous part in the causation, we may infer that these bacilli are thus aided in obtaining access to the whole economy. We claim that the tonsil being an open gateway for the reception of all forms of disease germs, it is plausible that it is liable to infection equal with Peyer's patches, etc.

Dr. LOUIS LAUTENBACH of Philadelphia read a paper on

THE NECESSITY FOR ACTIVE, NOT PASSIVE, TREATMENT IN EAR DISEASES.

It is my purpose to advise a more intimate study of ear conditions, and to present advanced methods of treatment. I am thoroughly convinced that by paying close attention to the ear chronic cases can often be materially improved and relieved, but especially do I advocate that upon the first evidence of any ear trouble it should be thoroughly examined, and if the physician feels himself incompetent to take charge of the case he should refer it to some one whom he knows will do justice to it. The policy of doing nothing at all, of letting diseased nature have its own way, is, to say the least, dangerous. What I protest against most strongly is the neglect of the family physician to give proper weight to the symptoms of ear disease in their incipiency, when a thorough treatment or two would dissipate the pathologic condition.

The importance the nose and throat bear to the ears has been recognized and has given rise to a false idea that ear diseases created by nose and throat trouble is curable through the nose and throat alone without local ear treatment; that the removal of the cause of the disease cures the disease itself. The removal of the cause is a necessity, surely, but attention to the changed ear condition is equally important.

To keep open the Eustachian tube, but especially to prevent any ossicular stiffening, membrane thickenings or adhesions I early use massage with the Siegle speculum or a phono or pneumo or mixed masseur of my own devising. I use the phono and mixed massage, as I find even early in cases of ear involvement there is often a tendency to a dulling of the sensitiveness of the auditory nerve from disuse.

By my masseurs I can produce any amount of suction force on the membrane I wish, with or without sound waves, giving any number of suctions I may deem advantageous, and can let the machine act upon the drumhead any period from a few minutes to several hours, if necessary. For this purpose I use machines actuated by electricity in which the suction is produced by a diaphragm operated by an electro-magnet; again a stronger one in which a suction pump is worked by an electro-magnet, and another in which a double suction pump is worked by a motor, this latter machine I am at present operating in connection with an ordinary Gramophone with an extra loud transmitter. These machines applied sufficiently early will frequently prevent the serious effects so often observed of rigid ossicles and thickened attached membranes and non-responsive ear nerves.

In cases of acute, active, painful middle-ear inflammation, I not only rely on dry heat, but am constantly using hot flaxseed poultices, and I must confess that I get remarkable results when they are used very hot and often. They will relieve pain and infiltration at times marvelously. Contrasting the results of the two methods, the passive serves to remove the exciting cause of the ear disease, depending upon the reparative powers of nature to restore the ear to normal. The other method endeavors to combat the pathologic ear processes and encourage nature to resume her normal sway. It endeavors to retain the full function of the conducting apparatus as well as of the ear nerves, and in every way possible strives to minimize the danger of any permanent disease of the ear or impairment of hearing.

There is another case of ear patients which has been almost totally neglected so far as direct ear treatment is concerned. I refer to the deaf mutes. I have succeeded in restoring one to such an extent that she can attend the ordinary public school course in Philadelphia, and another girl, 7½ years, from Shenandoah, now under treatment by me, has within the past few weeks given marked proofs of hearing, while at the same time she has learned to speak several words fairly plainly. Her facial expression and manner has become transformed from that akin to an idiot to a degree of intelligence. This has been accomplished, too, after she had been discharged from a deaf and dumb institution for the training of lip speech, on the ground, as I understand, that the child's brain was weak and inclined to be idiotic, and it would be useless to attempt to teach her. So far, in nearly all the deaf mutes placed under my charge, I have been able to develop some hearing, provided the caretakers followed my instruction. I consider the ear masseurs the important element in the treatment. It was with the conviction that my massage apparatus had helped me in my ear work that I presented the machines to the medical public some three years ago, and with the knowledge of the successful results obtained I have continued their use, modifying them as experience suggested, and I again present them here at this meeting as a method which opens up an entirely new field of ear treatment, with new possibilities not only for preventing the bad effects of ear inflammations, but for modifying and overcoming the results of such cases as have been neglected or have developed into chronic ear thickenings, membrane retractions, ossicular unions and sluggish nerves.

Dr. W. T. ENGLISH of Pittsburg read a paper on

THE ELEMENT OF FEAR IN HEMOPTYSIS.

He assumed that the extent of the fear and the neurotic perturbation are out of all proportion to the amount of blood expectorated and can not be interpreted except through the language of the emotions. After citing a number of cases exemplifying the fear element in hemoptysis he argues that the special study and treatment of this element is essential to success in the treatment of hemoptysis generally. To quiet the fear and the resultant neurotic tumult is as essential to the welfare of the patient as to cause a cessation of the blood spitting.

In hemorrhages of this character quiet is of first importance. This quiet can not be secured simply through enforced inactivity. We need calm which will diffuse itself with sure celerity through the nerve centers and plexuses, that will reach with its message of peace the remotest fiber of the nervous organism and restore the coördinations that have been lost through the element of fear as exemplified in hemoptysis. This rest is available through the hypodermic use of a decisive dose of atropia. Until this tranquility is secured all treatment will be experimental. It quiets the tumultuous demeanor of the central cardiac organ and restores its wonted rhythm. The unstable behavior of the peripheral vessels in the general circulation, as also in the pulmonary area, is replaced by a placidity that is at once restful and restorative. This quiescence is distributed equably and with promptitude and it is in this special direction that the efficiency of the atropia lies. It quickly and surely puts to rest the emotional elements that otherwise might continue indefinitely.

Moreover, the fact that atropia is rapidly diffused and quickly eliminated adds to its value in these cases. It becomes the duty of the physician to adjust the treatment to the element of fear as well as to the hemorrhage. If the hemorrhage is abundant the dosage should be large enough to paralyze the peripheral vasomotor nerves and thereby lessen blood pressure, causing a general determination of blood to the surface and thus relieving the vessels from which dangerous hemorrhages emanate. If the hemorrhage be small and the emotional manifestations, as exemplified through the element of fear be great, the dosage should be proportionate to the fear element and therefore must be generous. If there is a medium exhibition of both elements the treatment should prevail as in excessive hemorrhages. When the hemorrhage and emotion are at variance in any degree, that element which has the ascendency indicates the treatment as to the urgency, dosage and frequency of repetition. Fear must be judged of by its type, its intensity and its persistence, as also its immediate and remote influences, with the same caution as the hemoptysis.

Dr. I. C. GABLE of York read a paper entitled

APPENDICITIS WITH CASES.

The profession are more divided as to this operation perhaps than any other. When mild it may subside with no marked symptoms. The ulcerative form is seldom if ever from a primary catarrhal condition. Ulceration is due to fecal concretions and rarely to foreign bodies. The infective form may result from either. Recurrent and relapsing are not interchangable terms. Recurrent are those which repeat at considerable intervals; relapsing when the attacks are so close as to be almost continuous. In the first it would appear that there had been a recovery from the peritonitis while the appendicitis had continued. In relapsing there is no complete recovery. In mild types, starvation in its therapeutic sense, with such other as indicated. Delay is justifiable to avoid operation in absence of acute symptoms. He gave the details of some cases operated upon with success, others where operation was declined.

The officers for the ensuing year are: President, Dr. W. Murray Weidman, Reading; secretary, Dr. C. L. Stevens, Athens. The society adjourned to meet at Lancaster the third Tuesday in May, 1898, where the 50th anniversary will be celebrated, that being the place where the society was organized in 1848. About 300 members were in attendance. The afternoon of Thursday was occupied by an excursion on the Monongahela River by steamboat, and a visit to the Carnegie Plate Armor works.

Association of American Medical Colleges.

Pursuant to a call issued April 27, the Association of American Medical Colleges met in the Hotel Walton, Philadelphia, May 31, at 10 A.M.

Dr. J. M. Bodine, president, in the chair. Thirty-four colleges were registered. On motion of Dr. Larrabee, the Association resolved to adjourn to meet at the College of Physicians at 4:30 P.M., Tuesday, and thus secure the attendance of delegates known to be on the "Journal train." On motion of Dr. H. O. Walker a committee of three was appointed to consider the report of the Committee on the Codification of the Constitution. The Chair appointed Dr. J. W. Holland of Philadelphia, Dr. C. W. Kelly of Louisville and Dr. John Heffron of Syracuse on this committee. After some informal discussion the Association adjourned.

On Tuesday afternoon the Association met in the lower lecture room of the College of Physicians. Twenty-three colleges were represented, with the President, J. M. Bodine, in the chair. The minutes of the Atlanta meeting were read and approved.

The President's Address was then read and, on motion of John B. Roberts, ordered printed.

The Committee on Amendments to the Constitution then reported by its Chairman, Dr. J. W. Holland. After receiving the report each article of the constitution was taken up separately and then adopted as a whole as given in Journal, Vol. 28, pp. 796-7, corrected as follows:

Article II, Sec. 2. The college applying "shall be elected to membership if it receives the favorable recommendation of the Judicial Council and the favorable ballot of a majority of the colleges represented at the meeting."

Article III, Sec. 2. "In place of this examination, or any part of it, colleges, members of this Association, are at liberty to recognize the official *certificates of reputable* literary and scientific colleges, academies, high schools and normal schools, and also the medical student's certificate issued by any State examining board covering the work of the foregoing entrance examination."

Article III, Sec. 6. "(*b*) To graduates and students of colleges of *homeopathic* or *eclectic* medicine, as many years as they attended those colleges, provided they have met the previous requirements of the Association and that they pass an examination in materia medica and therapeutics. (*c*) To graduates of reputable colleges of *dentistry*, *pharmacy* and *veterinary* medicine, one year time."

Article V, Sec. 2. . . . "The seven members constituting the *Judicial Council* shall serve three years each. Vacancies by expiration of term shall be filled at the annual election of officers. Vacancies by death or resignation shall be temporarily filled by the surviving members of the Judicial Council."

The By-laws were unamended.

After some discussion, on motion of Dr. John B. Roberts, it was declared the sense of the Association that this constitution was in force for this time forward.

The Secretary's report was then read and approved.

Dr. J. P. Lord moved that suitable resolutions on the death of Dr. Perry Millard be prepared and spread on the records of the Association. The President appointed a committee for that purpose consisting of Dr. J. P. Lord, Dr. C. W. Kelly and the Secretary. This committee afterward reported as follows:

Whereas, We are reminded by the absence today of one who had been among our most active members, Dr. Perry H. Millard; one who was untiring in his devotion to the interests of this Association and the cause which it represents. In his death the Association has sustained the loss of its best friend, most earnest and faithful worker and wise counselor; the profession a true friend and exemplar; and this Association deplores his untimely death; therefore

Resolved, That we make this sentiment of our regard for him a matter of record; that it be placed among the minutes of our proceedings and that a copy be furnished his family.

The report of the Committee on Course of Study was read by title and ordered printed.

The recommendations and report of the Judicial Council were then read and approved.

The Medical Department of the University of Niagara was elected to membership.

The following named officers were elected for the ensuing year:

President, Dr. J. W. Holland of Philadelphia.
Senior Vice-President, Dr. H. O. Walker of Detroit.
Junior Vice-President, Dr. Thomas Opie of Baltimore.
Secretary and Treasurer, Dr. Bayard Holmes of Chicago.

Vacancies in the Judicial Council were filled by reëlection.

(Signed) Bayard Holmes, Secretary.

Judgment Against the Medical College of Ohio Resubmitted to the Council to Fix Penalty.

Whereas, By the unanimous decision of the Judicial Council of the Association of American Medical Colleges it was heretofore adjudged on May 31, 1897, that, "After due examination of all the evidence before us, and the statement of Prof. James G. Hyndman, secretary of the faculty accused, we find as follows: That the John E. Yarling specified in the charges was actually graduated at the said Medical College of Ohio as a Doctor of Medicine on April 9, 1897, and that the said Yarling matriculated for the first time in the Illinois Medical College in April, 1895, all of which is in violation of Section 5 of Article III of the Constitution of the Association of American Medical Colleges."

Now, therefore, as it appears from the action of the Association of American Medical Colleges held at Philadelphia on June 1, 1897, that the Judicial Council must fix penalties in the determination of all such matters as involve a violation of the constitutional requirements of the College Association, the Judicial Council decrees that: The provisions of Section 5 of Article III of the Constitution embody fundamental principles which must be held sacred and inviolate, and that the said Medical College of Ohio has forfeited its membership in the Association of American Medical Colleges.

The language of the Constitution is mandatory; Section 5 of Article III reads as follows: "Candidates for the degree of Doctor of Medicine shall have attended three courses of graded instruction of not less than six months each, in three separate years," prior to 1899. The Council has heretofore held that "no student can be admitted to a second course of instruction within twelve months from the date of the beginning of the first course," by any college holding membership in this Association, and that "no amount of previous study can be accepted in lieu of any part of any one of the three courses of graded instruction provided for in Section 5 of Article III of the Constitution."

(Signed) Dudley S. Reynolds.

James H. Etheridge.

I certify that this is an exact copy of the original, signed by six members of the Council. L. B. Baldwin, Clerk.

Fifteenth German Congress of Internal Medicine.

Berlin, June 9-12, 1897.

In his opening address von Leyden called attention incidentally to the danger that general therapeutics may be neglected in the modern development of specialism, and Virchow observed that for fifty years he had fought specialism, but had gradually become convinced of its utility, while still recognizing its menace to general science. This peril must be borne constantly in mind and no fundamental divisions allowed in spite of the numerous ramifications. He added that pathologic anatomy is the one thing common to all special branches, and yet the pathologists are on the point of organizing a special congress!

The first subject, "Chronic Articular Rheumatism," was presented by Professors Bäumler and Ott. After urging a more exact definition and limitation of the word rheumatism, the former reviewed the bacteriologic investigations: Schüller's bacillus (1892), and the small dumb-bell bacillus found by Bannatyne and Wohlmann in twenty-four out of twenty-five cases (1894), confirmed by Blaxall as a small, short, pole-staining bacillus found in the synovial fluid in eighteen cases of polyarthritis, and absent in other forms of articular affections. He succeeded in cultivating it on the usual media, except gelatin, but did not find it pathogenic in experiments on animals. Bäumler urged further research in this line. The preponderance of female subjects suggests the possibility that the genital mucosa is the route traveled by the exciting agent. He warned against the abuse of morphin, stating that the syringe should never be given over to the patient. He added that the term, *arthritis pauperum*, is incorrect; the well to-do are affected as often as the poor. Potassium iodid was recommended by Krönig, v. Noorden and others. Davidsohn recommended "fango," Battaglia mud. V. Noorden has been testing the lemon cure in this disease, and finds that it does no harm, and even produces a transient subjective improvement, but has no effect on the metabolism. He advises antiobesity treatment, as it often leads to increased mobility of the articulations. Schüller uses an emulsion of iodoform and guaiacol injected locally. Sixteen out of twenty-nine cases thus treated were completely cured. The injections are painful, and must be repeated in large joints three to seven times. Complete cure sometimes follows one injection in the case of small articulations. An operation is more rapid in its effects. He has operated sixteen times, eleven on the knee, with complete restoration of mobility. No relapses. Improvement perceptible in a fortnight.

Professor Ott in his address signaled the importance of trauma, dampness and lack of light and air in the production of the disease; recommended woolen clothing and especial attention to the diet, with meat for a foundation, combined with eggs, fish, vegetables, butter and cheese, especially milk. Water the best beverage; alcohol and carbohydrates much restricted; moral depression avoided; a journey to be advised in some cases. Treatment should be prompt and meet every stage of the disease, which should be carefully watched over even long after convalescence. Each acute symptom must be hastened past with every possible means: Fever by repose in bed and restricted diet; local pains and swellings with Priesnitz compresses, liniments or salves with opiates or injections of morphin. Absorption is accelerated by painting the surface with tincture of iodin. Puncture is also useful in severe swellings, and elastic bandages. He adds that the success of the salicylic preparations in acute articular rheumatism is only equaled by their ineffectiveness in arithritis deformans, not only at first, but in the exacerbations. Some find salol beneficial, others antipyrin, acetanilid, phenacetin, phenocoll and malakin. When there is more or less swelling of the joints, without much loss of mobility or dislocation of the ends, external treatment is indicated that will favor absorption, such as tincture of iodin and ichthyol, which sometimes score a success. When all the symptoms of acute or subacute inflammation have subsided, baths should be recommended. They should be suspended whenever inflammatory symptoms reappear, until they pass away again. In all baths the main point is heat. This can be wonderfully attained by the new partial steam and hot air baths (Tallermann's 104–119 degrees C.); mud baths produce a mechanical stimulation of the surface in addition to the heat, and partial mud baths for weak patients have been found useful applied as hot mud compresses, with occasionally surprising success. The simple hot springs, such as at Teplitz, Gastein, Warmbrunn, etc., are especially adapted to patients with much nervous excitability. The success of sulphur baths is probably due to the heat. He also recommends the hydriatic processes, which combine hot and cold baths, as an advisable supplement to a course of hot baths, to tone up the system debilitated by the effects of the heat. They also render it less liable to relapses. In the raw seasons it is better to resort at once to a hydriatic course. He also advocated massage as an important aid in the treatment, but if the capsule is already contracted, massage can not restore it. Active and passive movements should also be undertaken to prevent stiffness; especially useful in this respect is the Zander apparatus. The climate for persons affected with polyarthritis deformans should be warm, even, dry and sheltered from the wind, with hot springs convenient. These conditions are fulfilled at Battaglia in northern Italy for the spring and fall, Ischia, where there are natural hot springs and also natural hot sand baths, and Algiers. Medication should aim to strengthen and tone up the system: Iron, quinin and cod liver oil. The iron is best administered as syrup ferri iodat., which is especially effective in younger patients. Singer has cured one typical case of acute rheumatism with intravenous injections of sublimate.

Program of the Berlin Lepra Congress.

October 11–16, 1897.

GERMAN EMBASSY, WASHINGTON, D. C., May 21, 1897.

Dr. Albert S. Ashmead:—Referring to my letter of March 22 last, I have the honor to enclose a program of the International Conference of Leprologists, to be held in Berlin, Germany, from October 11 to 16 next. You will oblige me by stating its receipt. Yours very truly,

BARON THIELMANN, Ambassador of Germany.

IMPORTANT LEPRA CONFERENCE WHICH WILL MEET IN BERLIN, OCTOBER, 1897.

More and more of late the interests of scientific circles have been directed to the question of the spreading of leprosy. The public attention also has occupied itself actively with this subject. Therefore it seems to us, that now the favorable moment has come to lead the work by unanimous consent into the right grooves. We shall stand for this, that the disease, which everywhere is in a slow but contstant condition of expansion, be stopped by suitable measures. We are of the general opinion that anything good in this field can only be obtained by a strict program, whose object and means would be as comprehensible as possible. In this sense we have the honor to make an invitation to a discussion on the lepra question to be held at Berlin the month of October, 1897. Further details will be communicated hereafter. The preparative works have been undertaken by the undersigned,

E. EHLERS, Copenhagen.
G. ARMAUER HANSEN, Berlin.
R. KOCH, Berlin.
O. LASSAR, Berlin.

PROGRAM.

The beginning of the sittings is proposed to be for the time from Monday, October 11, to about Saturday, October 16. The deliberations will take place in the meeting hall of the Imperial Board of Health, 19–20 Klopstock Strasse, Berlin, N.W., which the Imperial government has placed at our disposition for that object. The time of the plenary sitting is from 11 A.M. to 2 P.M., in order to leave the members of the conference time for other consultations and possible sittings of commissions. An exhibition of all the objects interesting for the investigation of leprosy will be connected with this meeting. The object of the conference is, in the first place, a scientific discussion of the leper questions as well as of the methods recommended for the limitation and suppression of the disease within the limits of possibility. The result of the debates shall be formulated in such a manner that on the foundation offered by them further steps may be taken eventually for legislation, administration and by international arrangements. The scientific material in hand will be analyzed and sifted by the conference in such a manner that the governments of all the states interested may be enabled to take appropriate measures. An international scientific understanding is therefore the real task of the lepra conference and state medical tendency, the larger point of view.

In order to accomplish these objects as much as possible all lepra authors, known as such, are invited to attend. As a large number of these gentlemen have already promised to come the success of the enterprise is assured. The manner of the work is in common about as follows: The questions are previously prepared by reporters and as far as the object requires or permits it provided with discussable theses. These elaborations, written in German, English or French languages, which most of the participants are likely to understand, are printed as soon as they have been delivered to Prof. O. Lassar, 19 Karlstrasse, Berlin, N.W., and continuously sent to all the gentlemen who have promised to attend. In this manner everyone is enabled to choose for himself a position for the discussions and to advocate or combat resolutions. The printed works are not used for lectures. Thus all the time and labor will be spared for the meeting without putting any constraint to the expressions of opinions and literary activity of the reporters. The reports sent are in conjunction with the record of the meeting to form a permanent literary monument of the congressional work. The printing of them is, therefore, for the present considered as a confidential manuscript and not otherwise published. Tables and diagrams will be reproduced, as far as it is possible.

As themes we can at once mention the following, barring possible changes, for which the gentlemen whose names are also mentioned have offered themselves. As a matter of course, every correction or addition which the expected participants, learned societies, or state governments will be received with pleasure and is even requested. The committee is ready to meet, as much as possible, any further proposition of this kind. It also will be thankful for everything done personally or materially in the interest of the Leprosy Congress.

THEMES.

1. The place of leprosy among the infectious diseases: Dr. R. Koch.
2. Pathologic anatomy of leprosy, Dr. Rudolf Virchow, Berlin.
3. Histology of leprosy, Dr. P. G. Unna, Hamburg.
4. How far are we justified in considering the lepra-bacillus as the cause of the disease? Dr. A. Neisser, Breslau.

5. The attempts at culture of the lepra-bacillus, Dr. B. Campana, Rome.
6. Etiologic rôle: *a*, of heredity; *b*, of transmissibility, Dr. E. Besnier, Paris.
7. Alimentation and leprosy, Dr. J. Hutchinson, London.
8. The question of inoculability, Dr. H. Köbner, Berlin.
9. Does leprosy go directly from man to man, or does it go indirectly? Dr. Lie, Bergen.
10. The patent consequences of the emigration and immigration for the leprosy question, Dr. E. Arning, Hamburg.
11. Leprosy returning from the colonies into the great cities of Europe, Dr. Hallopeau, Paris.
12. General view of the condition of therapy, Dr. O. Lassar, Berlin.
13. Leprosy of the eye, Dr. Borthen, Drontheim.
14. Visceral leprosy, Dr. Doutrelepont, Bonn.
15. Anesthetic forms, Dr. Looft, Bergen.
16. Relations between syringomyelia, Morvan's disease, Aïnhum and lepra, Dr. Zambuco Pacha.
17 Optional or obligatory isolation, Dr. Armauer Hansen, Bergen.
18. The best arrangement of leprosies, Dr. O. Petersen, St. Petersburg.
19. Foundation of lepra societies, Dr Kirchner, Berlin.
20. Nomenclature, Dr. Dehio, Dorpat.
21. Historicals of leprosy, Dr. E. Lesser, Berlin.
22. Geography of leprosy: 1, general consideration, Dr. Kübler, Berlin; 2, Norway, Dr. Hansen; 3, Sweden, Dr. Sederholm; 4, Denmark and Iceland, Dr. Ehlers; 4, Russia, Dr. Pospeloff, Moskow, and Finland, Dr. Fagerlund of Helsingfors; 6, Turkey, Dr. von Dühring, Constantinople; 7, Greece, Dr. Rosolimos, Athens; 8, Bulgaria, Dr. Bogumil Berin, Sofia; 9, Roumania, Dr. Kalindero, Bucharest; 10, Hungary, Dr. Schwimmer; 11, Austria, Dr. Kaposi; 12, Germany, Dr. Blaschko, Berlin; 13, Italy, Dr. Pellezzari, Florence; 14, Spain, Dr. Zuriaga, Valencia; 15, Portugal, Dr. Seferino Falcao, Lisbon; 16, France and colonies, Dr. Feulard, Paris; 17, England and colonies, Dr. Phineas Abraham, London; 15, Holland and colonies, Dr. Broes Van Dort, Rotterdam; 19, Belgium and Congo, Dr. Bayet, Brussels; 20, Canada, Dr. A. C. Smith; 21, United States, Dr. White, Boston; 22, Central America, vacant, 23, West Indies, Dr. Numa Rat, St. Kitts; 24, Ecuador, vacant; 25, Colombia, Dr. Carrasquillo, Bogota; 26, Chili, Dr. Valdes Morel, Santiago; 27, Argentina, Dr. Sommer, Buenos Ayres; 28, Brazil, Dr. Silva Aranjo, Rio Janeiro; 29, Madeira, Dr. Goldschmidt, Paris; 30, South Africa, Dr. Impey, Cape Town; 31, Dutch Africa, Dr. Schön, Berlin; 32, Egypt, Dr. Engel Bey, Cairo; 33, China, Dr. Kerr, Canton; 34, Japan, Dr. Kitasato, Tokio; 35, Oceanica, Dr. Mouritz, Hawaii.

The Exhibition which is connected with the Lepra Conference will be held in the rooms of the Imperial Board of Health. It embraces exclusively scientific objects and is divided into the following sections: Anatomy and morphology, micrology, photography, cartography, bibliography. We pray that this Exhibition may receive abundant contributions. In the enclosed formulary please find the provisional indications of the sendings expected. Government Councilor, Dr. Köbner, member of the Imperial Board of Health, has undertaken the direction of the Exhibition.

Formulary:—The undersigned offers for the Exhibition of the Leprosy Conference for the group: 1. *Anatomy and Morphology.* 2. *Micrology.* 3. *Photography.* 4. *Cartography.* 5. *Bibliography.* The desired space is . . square meter table surface, . . square meter wall surface. The objects are sent by post, by freight, and will arrive at the latest September 15.

Signed, ...

PRACTICAL NOTES.

Paralysis of the Forearm from Bicycling.—Dr. Destot has published in the *Gazette des Hôpitaux* an account of his own experiences. An abstract of the paper appears in a recently published number of the *Neurologisches Centralblatt.* After a long ride he experienced paresthesia in the fourth and fifth fingers, with impaired sensibility and paresis in the interossei, lumbricales, and the adductor pollicis. The paresis was followed by distinct atrophy in the affected muscles. He considers the affection to be the result of pressure upon the branches of the ulnar nerve, aggravated, doubtless, by the vibration occasioned by bad roads. He also considers that predisposing factors existed in the softness of the skin of the hand and in the exhaustion of the muscles and the consequent loss of protection to the nerves lying in or under them.

Arsenious Acid Again brought out as a Cancer Cure.—The *Semaine Méd.* of May 1 contains photographs of three persons radically cured of cancer of the nose, one a woman of 84, with views of microscopic sections of the neoplasms, showing their character. The only treatment was painting the surface with a solution of arsenious acid 1 gram, to 75 grams each of ethyl alcohol and aq. dest. (reducing this amount to 40 grams each, as the eschar grows thicker). A little fresh blood is drawn to the surface, which is then painted with the solution, and left exposed to the air if possible. An extensive cancer requires daily painting for two to three months before the cure is complete. Cerny and Trunecek conclude their report with the statement that they have not succeeded in curing carcinoma of the mamma with this treatment, but that all surface cancers are relieved and rendered almost entirely odorless with it. It is perfectly harmless, as has been shown by cases of cancer in the buccal cavity treated for months without any evidences of arsenic intoxication, and it is indicated in every cancer of the skin without ganglionic indurations.

Uncontrollable Vomiting in Pregnancy, Continuing after the Death of the Fetus.—Fabre notes a case of uncontrollable vomiting in a primipara, 18 years of age, who had previously suffered from anemia and hysteria. The vomiting began at the fifth month of pregnancy and had continued up to eight and a half months, with increasing weakness. The fetal heart was not to be heard, yet the vomiting continued and medicinal means were of no avail. It was therefore decided to induce premature labor, and Krause's method (introduction of a bougie into the uterus) was employed. On the day before this was done the patient was so weak as to require injections of caffein and ether and 200 g. of artificial serum into the subcutaneous tissue of the abdomen. Twelve hours after the introduction of the bougie into the uterus a dead female fetus was delivered by means of forceps. The vomiting still continued and the patient died twelve hours later. The only lesions found at the necropsy were those of recent gastritis. The case is interesting, for the death of the fetus was not followed by a cessation of the vomiting, a circumstance probably due to the fact that here pregnancy was not the sole factor, but had superadded to it the pathologic state of the stomach.—*British Medical Journal.*

Ligature of Carotid Arteries for the Control of Hemorrhage due to Pharyngeal Abscess.—At a recent meeting of the Royal and Medical Chirurgical Society Clutton (*Brit. Med. Jour.*, May 29, 1897, p. 1349) reported the case of a victualer, 28 years old, with a history of having bled rather profusely the day before from an abscess in the pharynx above the right tonsil. After the lapse of a few days the soft palate was divided for the purpose of a complete examination of the abscess. A hole was found passing through the wall of the pharynx into the tissues of the neck. This opening was enlarged and the cavity plugged with cyanid gauze, as it was thought from the character of the hemorrhage that the bleeding might be from the internal jugular vein. During the night following this operation, the man bled so furiously that no doubt could be entertained as to the hemorrhage being from a large artery, probably the internal carotid. On the following day the bifurcation of the common carotid on the right side was exposed and an animal ligature applied by means of a stay knot to the common carotid and its two branches. A saline infusion of two pints was given whilst the wound was being closed with sutures. The wound in the neck healed by first intention, and the abscess cavity in the pharynx was found by digital examination to have closed some time later. There was no further hemorrhage after ligature of the carotid arteries.

The Treatment of Wounds of the Air-passages.—Platt (*British Medical Journal*, May 8, 1897, p. 1149) reports ten cases of suicidal wounds of the throat in which the air-passages were injured and appends the following summary: 1. Suicidal wounds of the throat should be treated by primary suture in all cases in which the general condition of the patient permits. 2. Antiseptic precautions are most important. 3. If necessary, chloroform should be administered, and is perfectly safe. 4. Divided muscles should be sutured, and in bringing together the edges of the skin the inversion caused by the platysma muscle should be corrected. 5. The wound in the air-passage should be completely closed. 6. In many cases it is quite safe to dispense with the use of a tracheotomy tube. If a tube be deemed necessary, it should not be introduced through the suicidal wound in the air-passage, but through a fresh vertical cut at a lower level. 7. Silk is the best material for suturing the larynx or trachea. 8. During the after-treatment it is unnecessary, except in certain special cases, to feed by a tube or by the rectum. 9. If the foregoing methods of treatment be adopted, not only will a large proportion of even dangerous and extensive wounds of the air-passages recover, but the period of recovery will be greatly shortened, the patient will not be exposed to the same risks of secondary inflammatory complications, and he will be much less liable to the occurrence of permanent stenosis of the trachea or the formation of an ærial fistula.

Successful Removal of Brain Tumor with Permanent Recovery.—Ziehl and Roth (*Deutsche medicinische Wochenschrift*, May 6, 1897, p. 297) have reported the case of a man, 60 years old, who, in the midst of perfect health, was suddenly seized with a peculiar rigidity of the thumb and index finger of the right hand, followed by loss of consciousness for several minutes, but without twitching or convulsion. With the return of consciousness vomiting took place. The gait was somewhat staggering, but there was no paralysis. On the following day the patient had returned to his usual health. Rather more than six weeks later the man was seized with transient tonic followed by clonic spasm of the right hand, without loss of consciousness. After another interval of about the same duration he was awakened at night by severe headache and found himself paralyzed on the right side. In the course of two weeks the palsy of the lower extremities had receded to such a degree that the man could walk, while that of the upper extremities subsided rather more slowly. From time to time, however, the right upper extremity was the seat of clonic spasm, always beginning in the thumb and index finger. At times the entire right side of the body was involved. These attacks were followed by headache, which was absent in the intervals. A small area of tenderness was detected in the right parietal region, which subsequently became edematous. No ophthalmoscopic changes were found. It was learned that the patient had had a chancre at the age of 23 years, but secondary symptoms had not been observed. Two or three years before coming under observation he had fallen and struck his head. The use of potassium iodid was unattended with relief, while mercurial inunctions were followed by amelioration of the headache following the attacks of loss of consciousness, although without effect upon the attacks themselves. Memory beginning to fail and the general condition to suffer, trephining was decided upon. Accordingly the motor area for the right thumb and index finger was exposed. The bone was found hard and dense and covered on its surface by hyperostoses and osteophytes. The dura was covered with a brownish-red mass resembling granulation tissue, a portion of which was adherent to the overlying and eroded bone. The adventitous material was removed, together with the involved bone, and the wound was tamponed and closed. Histologically the material was found to be constituted of round cells. The surgical progress of the case was uncomplicated, but the convulsive attacks recurred, and finally the condition of the patient became so aggravated that a second operation was undertaken at the site of the first, the dura being now opened and a collection of material similar to that found originally removed. This, on microscopic examination, proved to be an angio sarcoma. The operation was followed by right hemiplegia and paraphasia, and impaired sensibility in the right arm. Later, however, progressive improvement set in, with almost complete restoration of function, and this condition was still present more than two years after the second operation.

Two Cases of Brain Cyst, with Operation, and Recovery in One.—At a recent meeting of the Boston Society for Medical Improvement two interesting cases of brain-cyst were reported, in both of which operation was undertaken, resulting in the one in recovery and being followed in the other by death. The first was reported by Cabot (*Boston Med. and Surg. Jour.*, June 5, 1897, p. 533) and occurred in a man, 23 years old, who at the age of 11 was struck on the top of the head by a heavy stick. At the age of 21 he first noticed occasional numbness at the middle of the right thigh upon its anterior aspect, associated with tickling, and recurring every three or four weeks. After rather more than a year these manifestations appeared almost daily and were soon attended with contractions of the anterior muscles of the thigh and twitching in the abdominal region. The leg became rigid and rotated back and forth involuntarily. In a short while a severe attack occurred, followed by a general convulsion and loss of consciousness. As in the other seizures, the movements in this began in the right thigh. The attack was followed by vomiting. Bromids only partially controlled the paroxysms; amyl nitrite was somewhat more successful. The attacks now began to be followed by a feeling of paralysis and numbness in the right leg and later also in the arm and face. Aphasia succeeded upon one attack. Surgical interference having been decided upon, a square opening was made in the skull over the motor area of the left hemisphere, and after an interval of five days the wound was reopened and the bulging and feebly pulsating brain exposed. The cortex presented a yellowish appearance toward the upper part of the opening. In this situation puncture was made with a trocar, and was followed by a spurt of brownish serum. A small opening was made into a cyst cavity about the size of a pullet's egg and possessing a smooth yellowish brown wall and extending deeply into the brain toward its center. On account of the size of the cyst and its probable simple non-malignant character it was decided to treat it by drainage, in the hope of thus obliterating its cavity. Several large strands of loosely woven silk were accordingly introduced and brought out through an opening in the middle of the dural and cutaneous flaps. The patient made a good recovery from the operation and was free from symptoms for two months, when the aura began to return, and soon the motor-symptom manifestations also, together with headache. Hearing and vision on the right side also became impaired. It seemed probable from the symptoms that the cyst in the brain was refilling, and, accordingly, some fifteen months after the primary operation, the wound was reopened. At once brownish serum made its escape through a yellowish area marking the site of the cyst. The walls of the cyst were now removed as thoroughly as possible and drainage was established temporarily by gauze, but later by glass. Considerable fluid escaped for ten days; the drainage tube was kept in place for forty four days. For a time there were no further symptoms except on mental application, but subsequently even this became possible without serious discomfort. Some degree of paresis and sensory impairment persisted in the right lower extremity.

The second of the cases was reported by Elliott (*Ibidem*, p. 536) and occurred in a colored man, 59 years old, with a history of syphilis, who presented progressively increasing weakness in the right upper extremity, with convulsive movements. After exposure of the motor area of the left hemisphere and evacuation of a few drops of clear, rather viscid, brownish fluid by means of an aspirator, a knife was introduced by the side of the needle, giving exit to more fluid. Examination with a finger disclosed a cavity about the size of an English walnut, whose walls were lined with gelatinous-looking granulations. A drainage-tube was introduced into the wound and improvement followed. After nearly two months an attempt was made to obliterate the cyst by dissecting away the sloughing tissue and granulations lining its walls and packing the wound with gauze. In the course of fifteen days the sloughs had all come away and the cavity was lined with pale granulations. The patient remained under immediate observation only a short time longer, insisting upon returning to his home, where he died after an interval of three months. It is thought that the condition may have been a cystic glioma, although the surrounding brain appeared healthy.

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:
Per Annum, in Advance $5.00
Single Copies . . . . 10 Cents.
Subscriptions may begin at any time and be sent to
THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 61 Market Street (Occidental Buildings), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, Venetian Building, Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the *Editor*, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street *(Occidental Buildings), Chicago.*

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

INFORMATION WANTED.

It would greatly facilitate the prompt delivery of the JOURNAL to those members of the ASSOCIATION living in large cities, if they would kindly furnish this office with their street address in those cases where it is omitted from the wrapper of their JOURNAL, as we have been notified by the postmasters of the larger cities that second-class mail matter not having street address, would be placed in the general delivery to await call.

SATURDAY, JULY 10, 1897.

THE INDIVIDUAL AND PHYLOGENIC GOOD OF PLAY.

An eminent actor, Mr. **GEORGE GROSSMITH** of London, narrating on the stage his impressions of the United States, remarked how seriously the average American takes his amusement, all the popular plays, music and songs being of a sad and melancholy nature. Not only must we plead guilty to this stricture of the genial and good-natured actor, coming as it does from a layman, but from the view-point of the medical man we must further admit that the physician of the present day does not need to be a profound student of the stigmata of degeneration to have noticed that the tendency to play is lacking in idiots of all classes, and that this defect is directly proportional to the degree of mental weakness. Since recent pathology has done much to throw light upon certain physiologic questions, the foregoing remarks would seem to furnish material for an obvious inference.

Besides the many homely adages of condensed wisdom bearing upon the importance of play and recreation, we know that the activity expended in the form of play is a normal and necessary manifestation that greatly concerns not only the development of the young but the preservation of the adult.

As the zoölogical scale is ascended, we find the play instinct in various animals. The ludicrous performances of spiders is more suggestive of incitation than of any other imaginable purpose, says **ROMANES**, while **DARWIN** writes with fulness and particularity upon the love antics of birds; and others since his time have commented upon the play impulse in discussing the theory of natural and of sexual selection, which he says acts throughout all the higher dominion of the animal kingdom. From childhood days we recall to mind the skip and play of young lambs that our primers used to tell about, as well as the rompish sports and certain festal pleasures occurring in the hey-day of life, and making red-letter days in our career, all of which go to show the existence of an impelling force inciting to the performance of actions not the result of reflection and manifesting themselves in the form of sport, frolic, gambol, recreation, pastime or amusement.

This deep-rooted instinct observed in primitive tribes, though differing somewhat in details of manifestation, is in fact only a differentiated form of the same tendency existing in civilized communities. For instance, the group of games to which our backgammon belongs is ancient and widely spread over the world, as the ancient Mexican game of *patolli*, which appears to be of Asiatic origin. Similar instances of mimetism and the like have been observed among the Eskimo of Behring Strait and the Chuckchis of Arctic Siberia, the latter of whom play football, a fact of interest in connection with the remark of the Duke of Wellington, who said that Waterloo was won on the ball grounds of England. The Chuckchis being the only tribe of Northern Siberia that has not yielded to Russia, the existence of football among them may be looked upon as suggestive of the incitation that prompts the manly pastimes of a vigorous race.

While additional instances may be cited, it seems unnecessary to say more in order to justify the position that the play impulse, deeply implanted in the race, is one of the motor activities evolved from the central nervous system, and that many of its manifestations are not only essential parts of life, but things that have a conservational tendency and make life worth living. Military and naval statistics may also be cited to show the disappearance of certain epidemic affections after rigid discipline had been relaxed and liberty to indulge in proper sport was allowed. Moreover, the recreative effect of change by breaking up monotony in the treatment of many nervous diseases, is so well known to physicians that some of them go so far as to recommend an occasional spree for the benefit of health, and **HUFELAND** even says that it prolongs life. A study of the relative longevity of English and American statesmen shows the average usefulness and longevity of public men in England to exceed that of the American by ten years. Most public men in England are among the best and keenest sportsmen; but with us it is quite different. Even General **GRANT** could not swim and did not care to shoot or hunt, and the same may be said of nearly all the statesmen of the National Capitol. Imagine the effect on his constituents of one of our hayseed senators in a pink coat riding to the hounds, arrayed in a bicycle suit, or frequenting the golf links with the British ambassador.

Notwithstanding these well-recognized facts of sport and play, the deep interest that should be felt in the people's amusement still awaits a champion; and a philosophic study looking to the furtherance of the great cause of innocent recreation most fit for health, is yet a virgin science badly in need of an exponent. Moreover, we find among the various instances of fanatic folly many cranks and sham-pious who denounce anything like the manifestation of play or amusement as a wicked thing, because in their prudish and evil-thinking minds there still lingers the puritanic spirit which calls anything sinful that makes people feel happy. The time has come, however, when biologists and physicians may treat this apparently trivial and hitherto neglected subject with ordinary seriousness, and place the same on record.

Without enumerating the sports that improve the body and break up the vices of the mind, it may be said that just as long as mankind is endowed with the faculty of emotional expression, so will its demonstration in various forms continue to manifest itself. As a rule people must and will divert and amuse themselves, and nobody can prevent them. But in these days of excessive drive and over-pressure, when undue waste of vital energy shows itself to the clinical observation of the physician in the way of various nervous and brain diseases, the question of averting or mitigating such mischief comes to us as a serious problem.

The obvious solution lies in the encouragement of all innocent recreations as a compensating factor in the phenomena of life. Clearly, our people do not play enough. If we want to keep up the spirit of a race in which runs the blood of Robin Hood and the old Viking kings, the palestric element must enter into its pastimes. If we would hold the trident of Neptune and have a long run on the world's political stage, "the man behind the gun," as well as the political ruler, will be none the worse for having been trained in the manly school of rude play and rompish sport.

Therefore, we should do all we can to further the great cause of innocent sport and recreation that bring together men and women during leisure hours at such places as the tennis court, the hunt, the meet, the golf links. In the light of more humanistic ideals of the present day, we do not admit the ethical cogency that such amusements are wrong because they are worldly. We should strive to meet people with a simple word or two expounding "the gospel of relaxation," with a view to make life better and make human actions abler when prompted by the two great motor forces of life which incite in our subliminal self the source and spring of all human actions, namely, the preservation of the individual, and the continuance of the species.

THE MEDICAL MAN AND HIS MORALS.

The question has been raised, is the profession of medicine of such a nature as to ennoble those who follow it? Would the man who comes under its influence be the same as if he had not had this experience? It is not easy to determine this matter for each individual case, but if we consider medical men in their relation to the members of other professions, and the duties and obligations society thrusts upon them, as compared with what it expects of other men, we will find that certain facts are patent to show that there is a different standard of morals for the medical profession. And this standard if followed must influence the medical man for good.

But more than this, the every-day life of a healer of the sick is of such a peculiar character that it can not but exert a power for good on those who practice it.

Let us examine these premises more carefully. Society expects the minister of divinity to be as near perfect as it is possible for him to be; it expects him to be free from petty vices, to be honest, to be dignified; it in return respects him, accords him precedence in all its assemblies and public gatherings. The "cloth" will silence levity, will gain admittance without question, will be credited without doubt. Society places such men above others in the moral scale.

In a similar way, but to a less extent, the physician has the respect of society. In continental Europe the healer of the body has as dear a place in the minds of his patients as the healer of the soul has in the minds of his flock. No one can read the strong picture of the Scotch country physician drawn by IAN MACLAREN in "Beside the Bonnie Briar Bush" without instinctively feeling that it is a true one, and that the devotion of country people was real and not unusual. A life so spent, relieving suffering must surely react strongly on the mind and make it purer, nobler and higher than it otherwise would be. Society, as we said before, demands a certain seriousness of the physician; it demands wisdom, courage and quickness of perception, but more than this, it demands soberness. The man who is jolly, who is light-hearted, who is a clown, soon finds that such a temperament is not wanted in the sick room. It serves now and then, as when it whiles away the tedious hours of a primipara's labor, but the grave face, the thoughtful look, the gentle soothing and consoling tone is the most appropriate. Hence, as a class medical men *are* serious and sober.

The medical man again must be ever ready and on the alert; he can not give up his nights to carousing, even though his patients see him not; the morning comes and with it stern responsibilities, eyes must be clear and hands steady.

Society likewise asks that its medical men have a certain mannerliness about them; they must not be fops, or dudes, but they must be dressed in a becoming fashion, they must be cleanly in appearance and habit. Lastly, society wants the physician to be above material greed. In some countries it is improper for a medical man to sue for the collection of a bill. Fees are considered as marks of gratitude and not as a compensation for services.

Even in our own country among many of the foreigners it is customary for the patient to slide the fee into the physician's palm as if it were a present, and it would be thought very unbecoming in the physician were he to "look the gift in the mouth," or complain as to the amount.

Society does not ask the butcher or baker to supply meat or bread for nothing, or even on credit, but what reproaches it would cast upon the doctor who would refuse to visit a sick patient because he had no means or because the patient had not paid his bill. In our commercial days and in the cities the doctor is becoming more like the business man, but somehow the public will not consider him in that light, and dislikes him if he practices business methods.

The doctor is asked to give his services freely to every charity "under the sun" and to feel himself honored in being accorded the privilege of so doing. But the teacher, the lawyer and the musician are paid for their services; yes, and the chaplain too.

So much for the demands of society compelling physicians by an unwritten law to behave differently from other beings. Now as to the medical Code and its demands. Every organization of men, from that of the association of robbers to that of the church, has its peculiar code of ethics, which serves to influence every member for the good of all. These codes are oftentimes more powerful in governing the conduct of men than the law of State or the opinion of society. In no organization does the code mean as much as in medical organizations. From the time of HIPPOCRATES down to the present day fraternal feeling among medical men has been a common virtue. The oath of brotherhood is taken in all lodges, in workingmen's associations, even in the society of thieves and pirates, but in medical societies it has a deeper significance. It strives here to abolish the law of competition. The ignorance and mistakes of a weaker brother, which in the natural evolution of things would destroy him, are through the Code of Ethics covered up by the stronger and abler brother. Where a word might destroy the confidence that it has taken years to gain, that word is seldom forthcoming. When the patient is impatient and endeavors to displace his medical attendant in an abrupt manner he is usually prevented from doing so by another physician, and the Code forbids the latter to in any way throw distrust upon the work of the former.

Again, the Code establishes a fraternal feeling by making it almost obligatory for one physician to treat the members of the family of another physician. Almost obligatory we say, though never considered in the light of an obligation but rather in the nature of a duty.

The Code sets the pace and though many feel themselves not bound by its articles. all strive to live up to its spirit. It serves to take the "fight" out of the medical man, to wipe out of him all traces of the competitive brute. The law of trade is "strive to conquer others, succeed by downing others, build up on the ruins of others." The law of the medical Code is "one for all and all for one. Succeed only with others, strive to aid others." Avoid competition, avoid contention.

Remember this is not a church commandment that is only believed in by the Sunday-school boys and girls, but a living commandment that is practiced every day all over the world wherever physicians are organized.

Such men who refuse to abide by this Code and grossly abuse it speedily find themselves ostracized and the profession refuses to recognize them as reputable physicians, even though the world accounts them a comfortable living and a certain confidence. The medical Code therefore would have a tendency to make men nobler who come under its influence and to make them better. Thirdly, the daily life of the doctor, what does it mean? Does it signify anything to come in contact hourly with the ills of all classes of the community? Not only the physical ills, but all the moral ills, all the mental suffering of hundreds of families. Can any one remain unmoved by the spectacle that any ordinary physician encounters daily? The young girl of promise about to graduate, stricken with phthisis; the only child of devoted parents dead after weeks of suffering; the breadwinner sick in his room with typhoid, his little ones and patient wife wanting the necessaries of life; the debauched husband killing his feeble helpmate by obliging her to be the mother of many children, or infecting her with virus picked up in the brothel; the woman pregnant for the first time, the months of anxious preparation, the final suffering, the happiness on the faces of all when in the midst of extreme agony the child is born. Such are the daily scenes of the active family physician, and it is inconceivable to us how they can fail to affect any man no matter how morally obtuse he may be, and affect him for good. The confidences of women, of men, of young people, are his; the life of the community—the inner secret life is as open to him as the sky and yet so sacred is this trust that seldom do his most intimate companions know these secrets from his lips. In fact, a famous physician was but recently fined a large sum of money for divulging a secret he obtained in professional confidence, although he abused this confidence in order to prevent his own daughter from being made unhappy. Entrusted more often with important secrets than either the lawyer or priest, yet so great a reliance is placed in the morality of the doctor, that he is changed as the grocer is changed, often for the slightest reasons, and without fear that these secrets because of revenge will be divulged. The physician must never complain of his own troubles, he must give strength and consolation to the suffering, but he must not look for it from his friends. And yet when one sees how others bear their troubles and how great is the load that others have to carry, our own ills seem little indeed, and we learn to *bear* them without complaint.

Thus the daily life that a physician is obliged to endure, in close contact with disease, misfortune, misery, death, poverty and vice, we believe tends to ennoble him, to purify and strengthen him, to make him forbearing and forgiving, loving and patient.

Can any one visit daily a poor little sick child with the purpose of relieving its suffering, without learning to love it? And when at last it is well and gains each day in health and the worn-out mother pours blessings over your head and hails you as a veritable savior, can any one at such a time be cruel or mean? We doubt it.

Every one who studies medicine does not remain in the profession. A great number each year leave, and we contend that a few years' practice will drive out those who are evilly inclined, either making of them quacks and ostracized charlatans, vendors of nostrums or disreputable abortionists whom no respectable community recognizes, or it sends them over into other professions and trades.

All physicians are not angels. But what we mean is that having a certain moral foundation to start with, a man must become stronger and better as he is subjected to the experiences of a medical life. It is true that the profession of medicine offers certain temptations to do wrong which other occupations do not, and sometimes the physician makes ill use of the trust imposed upon him, but this is comparatively seldom, and when one considers the power a medical man has to do wrong and how many chances are open to him to commit crime, it is a wonder so few of the profession do become convicted criminals. It is asserted in some quarters that as the struggle for existence grows more severe more of the medical fraternity will be compelled to do wrong, will in other words degenerate, will perjure themselves for expert fees, will perform abortion, play the rôle of charlatan, etc.

This remains to be seen. Strong social forces are at work to oppose the competitive spirit and the situation may change before many moons, the struggle being lessened or done away with entirely.

Some may say that the physician is no better at heart than other people, it is only the fear of the law, the fear of being ostracized by his brethren and the fear of pecuniary loss which keeps him in the beaten path, and that when he can violate the Code without being discovered he does so; that he is hypocritical and apt to pretend knowledge of things he is ignorant of and that he ascribes to his own powers effects which are in all probability the results of natural causes.

Such criticisms are to some extent true, but they fail to affect the general statement; they rather strengthen it because what is thus condemned in the physician is permitted to the merchant and tradesman. Whether men abstain from evil from fear or because they love the right, the abstinence in itself produces changes which are lasting. And physicians, because they are compelled to lead such lives, must in time become changed so that what was once compulsion becomes natural and automatic.

THE CRITERIA OF SENILITY.

It is not infrequently the duty of physicians to decide upon the disqualifications from age, but he would be a rash medical authority who would formulate a general rule as to the exact period in life when all men should give up active pursuits and be considered as unfit for the ordinary duties of business or professional life. It is true that senile changes occur in perhaps a majority of those that reach any advanced age that disqualify them to a greater or less extent, but there is no uniformity as to this and it is impossible to lay down any law that is universally applicable. Moltke at past the age of 70 was the organizer of the most successful great campaigns of modern times, and Gladstone at a still greater age is influential and active to a degree surpassing most younger men. These are prominent instances, but they are typical of many less prominent ones, and it would be hard to say that there is any essential reason why a man may not be as good for counsel and as mentally active at 70 as he is at 50. Many men are not, it is true, and it would be an excellent thing if most men could retire at that age to a well-earned leisure and ease. This is not the case, however, with very many, and there are others still whose retirement would be a public loss.

While our profession has never fixed the period when senility can be said to disable, legislative and and judicial authorities have been more willing to attempt it, and it has been legally decided in at least one State of our Union that after the not very excessive age of 66 a man is entitled to at least the privileges and exemptions that old age should be *allowed, no* matter what may be the bodily vigor or the capacity for mental work. It is a natural and proper thing that a certain age should exempt from active military service, though it is notorious that the fixed age of retirement of army officers seldom is willingly accepted by the individuals, who generally, and often correctly, believe themselves still capable of good service. There are other reasons, however, than their disability for this limit and it is likely to stand, especially as the government can still claim their services in emergency. There are other departments of the public service where there is no apparent age limit, and where senility, understanding by this the mental failure of old age, can be most serious in its consequences. It is a curious fact, moreover, that judges who give the decisions as to the age limit, themselves, habitually pass beyond the limit they set, while still in active life. Our supreme courts are largely made up of old men, and it seems to be one of the facts of human experience that courts that possess the highest reputation and authority are chiefly found among those that are thus composed. Some time ago there were published in a leading English periodical some criticisms of the British higher courts of justice based on the ages of the judges who, it was claimed, showed senile infirmities that ought to disqualify them for their positions. English conservatism, or perhaps we should say English common sense, has not been affected by these criticisms and the British bench still contains its octogenarians. In this country, too, we have aged judges as well as aged physicians still in active exercise of their professional functions, but it is only on the higher judicial bench that this is frequent enough to almost be the rule, and there is here a possible danger that is worth considering, even if it be but slight. A business man or a physician is, as it were, constantly on trial, but a judge is the arbiter himself and his duties are not such as would be so seriously embarrassed by a physical incapacity that would disable one in another life pursuit. He is therefore protected to some extent against the disabilities of age, while some of its infirmities may be already upon him. Are aged judges always the best court of last resort in questions where senile incompetency is involved, even when especially qualified to interpret the law on other points? This is a question that may sometimes arise, and, it is possible, injustice has been done in some instances by the unconscious prejudice of old men against what they may feel to be a reflection against themselves. This is only an example of the medicolegal suggestions that arise in the consideration of this subject.

What is wanted is, as Minot has said, a more complete study and review of the facts of senility and its effects, and some authoritative expression of the latest and fullest acquisitions of medical science in regard to it. It is not necessary to have a fixed period when a man can be said to be aged; some men are older mentally and otherwise at 50 or 60 than are others at 80. What we need is a better and fuller knowledge of all the general laws governing senile changes to and in the judgment of any individual case, a better body of scientific doctrine to govern the making and the application of general and special rules. This is one of the desiderata of modern medicine, and is equally needed for the guidance of courts and legislators, as well as for the better instruction of the public, who are at present inclined to exaggerate the disadvantages of age, often to the great hardship of the individual.

CORRESPONDENCE.

The Reorganization of the Public Hospitals in New York in 1895 and the Present Attitude of the Profession on the Subject.

New York, July 1, 1897.

To the Editor:—Two years ago the profession of this country was somewhat startled by the announcement that twenty-eight or more physicians who were serving gratuitously in the hospitals in the Department of Charities of New York were about to be set adrift without cause or pretext, except that the medical colleges clamored for their places. Surprise was heightened when it was made known that in spite of the protests of the veteran members here threatened with dismissal, and the repeated appeals of the local medical societies, the medical colleges defiantly proceeded to nominate physicians for places not yet vacated.

This procedure stirred the general profession into prompt and vigorous action, as it certainly seemed to involve the violation of one of the basic principles of the Code of Ethics of the American Medical Association.

The County Medical Association of New York—that medical organization which has remained loyal to the American Medical Association—immediately appointed a committee on "The Relation of Physicians to Public Hospitals," which at once cited every member connected with any teaching corporation to appear before it and explain or justify their action. At the same time a circular notice was served on them, requesting that "they take no action in the nomination of candidates for positions not yet vacated until those about to be removed have had charges preferred against them, or have had an opportunity to be heard in their own defense." But this notice was in every instance ignored, when the work of retaliation was begun; the fiercest blows being first directed against the medical school which occupied the public grounds covered by Bellevue Hospital.

Here the avenging hand of retaliation was first felt, and the city authorities were forced to serve notice on Bellevue Medical College to move off public grounds, when the faculty moved across the way and for a week or two joined forces with the University Medical School. Next this Committee appeared before the Commissioners of Charities and demanded one half of all the medical-staff appointments in the hospitals of New York for members of the profession at large, such appointments to be submitted by the medical societies. This proposition was received as acceptable and it was promised to be put into effect.

Matters finally came to a climax at the June meeting of the New York County Medical Association, when the following resolutions were presented by the Committee on Hospitals and adopted by the Association:

"1. *Be it resolved*, That after a thorough and impartial investigation by the Committee on Hospitals and Dispensaries of the New York County Medical Association, it now be declared the sense and belief of this Association that the reorganization of the medical service in the public hospitals in New York in 1895, as far as it concerned members of the medical profession, involved a violation of the Code of Ethics of the AMERICAN MEDICAL ASSOCIATION, was vicious in principle and unjust in its effects.

"2. *Be it resolved*, That this Association deprecates and condemns the present system on which the medical management of the Department of Charities is conducted and with the advent of Greater New York unconditionally pledges itself to leave nothing undone to effect its early repeal."

Immediately on the passage of these resolutions all formal charges against members, it appears, were withdrawn.

At the time of this reorganization upheaval in New York the JOURNAL took the ground that it was a humiliating spectacle to witness the wholesale removal of medical men without any adequate justification or pretense.

It is now to be hoped that the voice of the profession has been heard in unmistakable terms, and that means may be devised by which an honorable and equitable adjustment may be arranged and the profession once more united.

JUSTITIA.

A Literary Endorser.

SPRINGFIELD, ILL., June 21, 1897.

To the Editor:—Allow me to call your attention to the following facts and enlist your coöperation in assisting this gentleman in a way that it seems to me he richly deserves from our profession.

One of the most glaring frauds of this decade has been an appliance known as "Electropoise," advertised in *Harper's Monthly* and other leading publications. The sale of this appliance has been fostered by the certificate given its promoters by one W. H. DePuy, assistant editor for some time of the New York *Christian Advocate*, whose official position on one of the leading religious papers of the country added some weight to his statements.

Recently I received an advertisement of "The University of Literature," edited by W. H. DePuy, A.M., D.D., LL.D., who I find is the clerical endorser of Electropoise. I wish you would call the attention of the 125,000 medical men in this country to the facts in this case, so that they may treat the compilations of the Rev. DePuy with the scant courtesy which they deserve. I send you copies of the advertisement of the Electropoise and University of Literature herewith.

Yours very truly, GEO. N. KREIDER, M.D.

PUBLIC HEALTH.

Rates of Mortality in 1896 in Thirty-two Large Cities.—From the last registrar-general's report (London) and from other official sources the following death rates for 1896 have been compiled. The cities are listed in the order of their reported low rates of mortality: Frankfort-on-Main, 15.6; La Hague, 16.3; Stockholm, 16.8; Copenhagen, 16.8; Edinburgh, 16.9; Cincinnati, 16.9; Genoa, 17; St. Louis, 17.3; Amsterdam, 17.4; Hamburg, 17.5; Berlin, 17.9; Brussels, 18.2; London, 18.6; Rotterdam, 18.6; Nice, 18.6; Paris, 19; Rome, 19.1; Turin, 19; Philadelphia, 19.8; Dresden, 19.9; Brooklyn, 20; Glasgow, 20.4; New York, 21.4; Vienna, 22.3; Boston, 22.5; Munich, 23.2; Venice, 25; Breslau, 25.1; Buda-Pesth, 25.4; St. Petersburg, 30.9; Calcutta, 33; Bombay, 41.5; Alexandria, 42.4; Cairo, 55.2.

Inroads of the Bacilli.—The report of the city bacteriologist of Syracuse, N. Y., shows that during the year 1896, 600 cases of suspected diphtheria were examined. Of these, 223 proved to be true diphtheria. In 411 cases given a secondary examination to see that the throats were free from the disease, as shown by the culture test, fifteen days were found to be the average time of persistence of the diphtheria bacillus in the throat. The greatest number of cases occurred in October. Of the 223 cases, 102 were those of children 5 years old and younger, and only 17 persons were over 20 years of age. In 150 cases the tonsils alone were involved. In 187 cases the diphtheria bacilli were found alone and in 36 cases mixed with some form of cocci. In 26 of the 36 cases that resulted fatally, antitoxin was not used, while the remaining 10 cases were moribund when first seen. Examinations for tuberculosis numbered 223, and of these cases 113 were found to have tubercle bacilli present.

Judgment of Board of Examiners Conclusive.—Another victory for the cause of higher requirements has been won. It is in the decision of the case of Van Vleck v. Board of Dental Examiners, which the supreme court of California handed down March 29, 1897. A writ of mandamus had been granted, to compel the board to issue to the petitioner a certificate entitling him to practice dentistry. But the supreme court holds that there was no cause of action stated, and reverses the judgment granting the writ. Its decision turned on the construction to be given to the California statute, approved March 12, 1885, entitled "An act to insure the better education of practitioners of dental surgery, and to regulate the practice of dentistry in the State of California." It provides a board composed of expert practitioners, with power to examine and license those who have not graduated elsewhere, and to investigate and pass upon the reputability of schools and colleges issuing certificates or diplomas, and the right of the holders of such diplomas to their possession. The powers thus conferred, the supreme court says, are broad and comprehensive and, in some respects at least, must in their nature be final. The judgment of the board, for instance, as to the qualification of an applicant for license by examination, which is largely if not wholly discretionary, it holds, must of necessity be conclusive. And the requirement to "indorse, as satisfactory, diplomas from any reputable dental college, when satisfied of the character of such institution, upon the holder furnishing evidence satisfactory to the board of his or her right to the same," it maintains, implies quite as necessarily the exercise of judgment and discretion as in the examination of an applicant as to his fitness; and that the board's action thereunder is final, and not subject to the mandatory control of the courts. On the other hand, if the statute had required that the applicant make a prescribed showing in a particular manner, and that thereupon the board should indorse his certificate, the court says that it might with some reason be said that the act was more ministerial than judicial, and that, upon the prescribed showing being made, the board could not refuse to act. The allegations that the American College of Dental Surgery "was a reputable college, and there existed and was at the command of defendants sufficient evidence of such fact," and that the petitioner furnished "evidence satisfactory to defendants that he was the person named in said diploma," the court further holds, were not the legal equivalent of an allegation that the defendant board had so found, and hence furnished no basis for the issuance of a writ of mandamus.

Health Regulations in the Adirondacks.—*To the Editor*:—Our Board of Health recently adopted the following ordinance concerning the sale of milk and cream in this village:

AN ORDINANCE CONCERNING THE SALE OF MILK IN THE VILLAGE OF SARANAC LAKE.

SECTION 1. No milk or cream shall be received, kept, offered for sale or delivered in the Village of Saranac Lake after the 20th day of June, 1897, without a permit in writing from the Board of Health, and subject to the conditions thereof.

SEC. 2. Every person applying for a permit to receive, keep, offer for sale, or delivery of milk or cream, must register his or her name and residence in a book kept for that purpose in the office of the Board of Health, file a certificate with said Board from a qualified veterinary surgeon, or such other person as the Board of Health may designate, certifying that he has inspected all of the milch cattle of the applicant from which such milk has been drawn; that they have been found sound and healthy, and that the dairy and other appurtenances necessary to the business are kept in a cleanly and proper manner. Any failure to comply with and maintain the conditions herein set forth shall be a sufficient ground for the immediate cancellation of such permit.

Sec. 3. Any person violating any of the provisions of this ordinance shall suffer and pay a penalty of $25 for each and every offense.

Adopted April 10, and amended May 15, 1897.

E. S. McClellan, M.D., }
W. F. Roberts, } Board of Health.
H. L. Lobdell, }

Attest:
F. P. Calkins, Secretary.

In view of the requirements of this ordinance, the dairymen supplying the village with milk, through the assistance of the Board of Health, procured the services of Dr. Cooper Curtis, a veterinary surgeon of national reputation, to inspect and test their cattle. A physical examination was made and the tuberculin test applied to the cattle of all the herds, aggregating 220 head. Every animal was found free from tuberculosis and otherwise in a sound and healthy condition. This remarkable immunity from tuberculosis is perhaps in some measure due to the hardy character of our native cattle, as rarely any importations from foreign herds occur. Scattered throughout this section there are always a considerable number of consumptives, many of whom ramble over the pasture fields and expectorate on the grass, and some fears were entertained by the laity lest the cattle might be infected by swallowing infected sputum; but experience seems to demonstrate that tubercle bacilli do not germinate in the vigorous stomachs of our native cattle.

Very truly yours,
E. S. McClellan, M.D.

Saranac Lake, N. Y., July 5, 1897.

Liability of City for Health Officer Burning Property.—The evidence in City of Dallas v. Allen showed that the city authorized its health officer, during an epidemic of smallpox in that city, to burn property which in his judgment was infected with the disease, when in his judgment it was necessary to do so to prevent its spread. In the execution of this authority he caused a house to be burned with its contents. This suit by the owner of certain of the contents, against the city, the health officer and the sureties on his official bond followed. The district court directed the jury to find against the city and in favor of the other defendants. April 14, 1897, the court of civil appeals reversed that judgment and remanded the cause. It says that the chief question was as to the right of the city to destroy property in the exercise of the power conferred on it by its charter, to all acts and make all regulations which may be necessary for the promotion of health or the suppression of disease. It thinks that the governing rule is found in a decision of the supreme court of Texas relative to the destruction of a house by the fire department, where it held that property can be so disposed of without the city or its agents becoming liable; that such a taking does not violate the constitutional pledge that private property shall not be taken, damaged or destroyed for or applied to public without adequate compensation being made, unless by consent of the owner. But the court of civil appeals thinks that a necessity for the demolition of the building for the purpose of checking the progress of the fire would have to be shown by the city, and the destruction of a house in an isolated place that could constitute no agency in communicating the threatened danger, would not be justified. And it holds that to the same extent that a city can destroy the property of a citizen in checking a fire it can do it in stamping out an epidemic, with exemption from liability. There being in this case evidence both to the effect that the articles in question could and could not have been rendered innocuous by a simple process of disinfection, the issue of fact thus raised, it holds, should have been left to the jury to decide. Furthermore, the city having directed or authorized the destruction of the property, if it was wrongfully destroyed, the court holds that the city could not escape liability.

ASSOCIATION NEWS.

Amendment to Constitution.—The following amendment to Article IV of the Constitution and By-Laws was offered by Dr. Wm. LeMoyne Wills, of Los Angeles, Cal., in the general session on Friday, June 4, 1897, but was received too late to be incorporated with the printed minutes of the general sessions:

Art. 4. Officers. The officers of this Association shall be a president, four vice-presidents, one secretary, one assistant secretary, a treasurer and librarian. They shall be nominated by a special committee of one member from each State represented at the meeting and shall be elected by vote on a general ticket. Each officer shall hold his appointment for one year and until another is elected to succeed him.

Resolutions Against the Antivivisection Bill.—The Permanent Secretary has sent the following circular to the Senators and Members of the House of Representatives:

Philadelphia, Pa., June 29, 1897.

Hon. ——, U. S. Senate, Washington, D. C.

Dear Sir:—The following resolution was unanimously adopted at the annual meeting of the American Medical Association in Philadelphia, June 2, 1897:

Whereas, Senate Bill 1063 (formerly Senate Bill 1552) has been reported favorably to the United States Senate; and

Whereas, We believe that its passage would seriously interfere with the progress of practical medicine, and therefore be a public calamity; therefore, be it

Resolved, That the American Medical Association, with a full knowledge of the contents of Senate Bill 1063, most earnestly protests against its enactment.

The day following the adoption of the above resolution, the Association, in general session, after listening to the address on surgery by W. W. Keen, M.D., directed, with the greatest unanimity and enthusiasm, that the following extract from his address be added to the above resolution, to be forwarded to the Senate, and later directed that a copy of the entire address should be forwarded to each member of the Senate and House of Representatives:

Animal experimentation has had also a very large share in the development of modern surgery. The whole question of the introduction of animal ligatures was begun in America by Physick, who used buckskin, and his follower Dorsey, who used kid and cut both ends short, Hartshorne, who used parchment, and Bellenger and Eve the tendon of the deer, and has been solved principally by experiment upon animals in order to determine accurately the behavior of such ligatures in the tissues. Only professional readers can appreciate what a boon to humanity this single achievement has been. Modern cerebral surgery also owes its exactness and success almost wholly to cerebral localization and antisepsis, both of which were first studied upon animals and later by the application of the knowledge so gained to man. Bacteriology would not now exist as a science, nor would accurate modern surgery and a large part of modern medicine be possible, had experiments upon animals been prohibited, as some zoöphilous women who love dogs better than men and women, and even little children, desire.

The foregoing resolutions of the American Medical Association were adopted by unanimous vote at its annual meeting, when the registration of delegates present was almost two thousand. The total membership of the Association is over eight thousand, from every State and Territory of the United States (except Wyoming) representing over one thousand State and county medical societies.

Commending these resolutions to your favorable consideration and enclosing a reprint of the bill in question. I remain,

Very respectfully, (Signed) Wm. B. Atkinson, M.D.,
Permanent Secretary.

SOCIETY NEWS.

The International Medical Congress.—A letter received from the Secretary-General of the twelfth International Medical Congress conveys the following information which is additional to that which has been published in the medical journals. As it is too late to send tickets to the American congressists, they are requested to send to the Secretary-General at Moscow their addresses in London or Berlin, or Vienna, or Paris, or to avail themselves of the National Committees in those cities, in order to receive their tickets and free passes over Russian railroads in those places. The free passes are valid from July 13 to September 13 over the following routes: Eydtkunen to Moscow, back; Moscow to St. Petersburg, or Moscow to Graniza, or Moscow to Odessa or vice versa; Graniza, Warsaw, Moscow and return by Moscow, St. Petersburg (or Odessa, or Eydtkunen, or Ungheni, or Alendrowo) or vice versa. Different lines going and returning may be chosen, and stop over is permitted. Eydtkunen to St. Petersburg is excluded from the free list. A. Jacobi, Chair. Amer. Nat'l. Com.

NECROLOGY.

Benjamin H. Throop, M.D., of Scranton, Pa., who died June 26, was a man of mark and influence not only in Scranton, but throughout Pennsylvania, and the long biographies of him in his home newspapers contain some interesting facts. Though he was the first settler and the first house-builder in Scranton, he was born in Oxford, Chenango County, N. Y., November 9, 1811. His family came there in 1800. They were of the Puritan revolutionary stock, both his father and grandfather having belonged to the Fourth Connecticut Volunteers under Washington. Dr. Throop studied medicine in Fairfield Medical College, Western New York, graduating in 1832. He first settled in Honesdale, Pa. After short but successful periods of practice there and in Oswego, N. Y., he settled in the town of Providence, in the Lackawanna Valley of Pennsylvania, in 1840, but in 1847 moved to what is now the town of Scranton. He procured the completion of the Delaware, Lackawanna and Western Railroad and the extension of the Delaware and Hudson Railroad to Scranton. He obtained the first charters for gas and water, and for a hospital in the town. He laid out the suburbs now known as Hyde Park, Providence, Dunmore, Priceburg and the town of Throop. He secured the creation of the Luzerne County out of Lackawanna County. He was the first postmaster at Scranton, founder of the Lackawanna Hospital, trustee of the Danville Insane Asylum, president of the Illuminating Heat and Power Company and the chief medical adviser for many years of the railroad companies running into the city, which now numbers over one hundred and twenty thousand people. He was the first surgeon from his county in the war for the Union, taking charge of the Eighth Regiment of Pennsylvania Volunteers, and afterward of the One Hundred and Thirty-second Regiment of that State, and he established a system of Hospitals at Chambersburg and at Harper's Ferry, as well as a system of medical relief in the field, which became general throughout the Northern armies. There were no public interests in which he did not take an active part, and, while he retired from the practice of his profession many years ago, his energy in affairs was unabated to the end. About three years ago he celebrated his golden wedding.

William C. Wey, M.D., Albany, 1819, for many years Health Officer of Elmira, N. Y., died of apoplexy June 30. He was President in 1871 of the New York State Medical Society and was also President of the Board of Managers of the New York State Reformatory.

John Frelinghuysen Talmage, M.D., New York University 1859, of Brooklyn, N. Y., died in Rye, N. Y., June 30, while on a visit to his daughter, the wife of Congressman J. Murray Mitchell. He was 64 years old.

James Cavanaugh, M.D., Easton, Pa., June 28, aged 67 years.——John Norwood, M.D., Columbus, Ga., June 28, aged 60 years.——Albert S. Rogers, M.D., Pavilion, N. Y., June 30.

MISCELLANY.

A Deserved Compliment.—Prof. Virchow is to be elected a Foreign Associate of the French Academy of Sciences.

Decrease of the Birthrate at Home.—A recent table makes the birth-rate of the United States in 1890 only 26.68 per thousand whereas in 1880 it was 30.95.

Plague Commissioner Rand not Dead.—So far the reports from Bombay of June 24, indicate that Commissioner Rand, wounded by a native while leaving the Governor's reception, was still living although in a precarious condition.

Etiology of Yellow Fever.—At the request of Dr. Freire the Government of Brazil has appointed a committee of seven prominent physicians to investigate his claims in regard to the micrococcus xanthogenicus.

Duty in Selecting Surgeons.—The supreme court of Iowa holds, in the case of Maine v. Chicago, Burlington & Quincy Railroad Company, April 8, 1897, that it was the duty of the company, under its contract with the relief department which it organized whereby it was required to furnish an injured employe surgical aid and attention, to exercise due care and diligence to select surgeons who were reasonably competent to treat him, and, if it did so, it was not liable for the negligence of the surgeons in treating and caring for his injuries. An allegation that a surgeon "either lacked the requisite skill or failed to exercise the same," the court says, does not show that he was in fact unskilful, nor that the railroad company was negligent in employing him.

Discharge from Insane Asylum after Escape.—The California statute concerning the management of the insane asylum at Napa provides that the resident physician shall be the executive officer of the institution, and shall discharge such patients as, "in his opinion, have permanently recovered their reason." Under this provision, where the physician had come to the conclusion that a patient was restored to reason, and had intended to order his discharge if his condition did not change in a few days, the supreme court of that State holds, in people v. Geiger, April 7, 1897, that the fact that the patient had in the meantime escaped, and was not present when his discharge as "recovered" was entered of record by the physician, was no ground for impeaching the physician's act.

The Sensational "Affaire" Thomson at Paris, mentioned in these columns at the time, resulted in the condemnation to five years imprisonment of the two physicians involved. Whether legally liable or not, Dr. B. was certainly indiscreet in curetting the uterus of a woman without ascertaining whether she was pregnant or not, and with such a lack of skill as to extract loops of the intestines through the cervix, not to mention the impropriety of performing such an operation (for which there was not the slightest excuse of urgency) on his dining table, with the assistance of his cook and coachman. He was on the staff of the *Revue Médicale*, and this magazine denounces Brouardel's expert testimony in the bitterest terms. Nothing seems to have been proved against Lajarrige except that he had directed Miss Thomson to Boisleux.

Not Hospital "Treatment."—One of the questions in an application for life insurance was as to whether the applicant had ever been under treatment in any hospital, asylum or other institution. This was answered, "No," in the case of Chinnery v. United States Industrial Insurance Company. But there was evidence that some twenty-five years previously something had blown into the applicant's eye, that she went to a hospital, by appointment, to have it removed, and returned the same evening. This, the appellate division of the supreme court of New York holds, April 6, 1897, was not being "under treatment in any hospital" within the meaning of the policy. It adds that it had nothing to do with the general health of the assured, and if it had been known to the company, could not possibly have been considered by it as a reason for refusing to issue a policy of insurance.

H. D. Didama, M.D.—A dinner was given in honor of Henry D. Didama, M.D., on the occasion of his fiftieth anniversary as a practitioner of medicine, by the faculty and the Alumni Association of the College of Medicine, Syracuse (N.Y.) University, on Wednesday evening, June 9. Dr. Nathan Jacobson acted as toastmaster. Eulogistic speeches were made by Dr. E. D. Ferguson, Dr. A. Vanderveer, Dr. Matthew D. Mann, Dr. Wm. S. Ely, Dr. Robert L. Morgan, Dr. Brace W. Loomis, Dr. Henry O. Marcy, Dr. John Van Duyn. Speeches were made by Chancellor James R. Day, Dean James B. Brooks, Rev. George B. Spalding, Hon. Frank Hiscock, Hon. Carroll E. Smith. The occasion was one long to be remembered by Syracuseans, and Dr. Didama's colleagues in the Association throughout the country join in congratulations.

Domestic Remedies in the Retrospect.—The *N. Y. Evening Post* of July 3 in a running summary of "The American Frugal Housewife" printed in 1835, refers to several expedients for home treatment. The usual precaution "before sending for the doctor" appears to have been omitted. To prevent lockjaw, lye, a rind of pork, strong soft soap, spirits of turpentine, and pulverized chalk are recommended; for throat distemper, the old name for diphtheria, a poultice of roasted apple mixed with an ounce of tobacco, the whole wet with spirits of wine and spread on a linen rag to be bound about the throat, is a panacea; to stop the blood from a wound apply scrapings of sole leather; a spoonful of ashes stired in cider is suggested to relieve nausea in cholera morbus. A salve to reduce inflammation in wounds is made from lard melted and cooled five times in succession, then simmered with sliced onions, and once more cooled; low-blackberry tea is prescribed for calomel sore mouth.

Colleges.

The annual commencement of the Yale Medical School was held June 30. About thirty new doctors received degrees.——Merced University has conferred the degree of LL.D. on W. A. Adams, M.D., Chief Surgeon of the Fort Worth (Texas) and Denver City Railway Company.——The Maine Medical School, Bowdoin College, at Brunswick on June 23, presented thirty-four diplomas.

Societies.

The ninth June meeting of the Dubuque (Iowa) Medical Society was held June 30.——The Eastern Iowa District Medical Society met at Washington, Iowa, June 24. The new officers chosen are Dr. W. B. La Force of Ottumwa, president; Dr. Grimes of Wapello, vice-president; Dr. M. C. Carpenter of Fairfield, secretary and treasurer.

Hospitals.

A new free hospital was opened by the Christian Hospital Association, Los Angeles, Cal., July 1.——The Salem (Mass.) Hospital is the recipient of $10,000 for the establishment of a home for convalescents, a memorial to William G. Webb, who at the time of his death (May 17, 1896) was president of the hospital corporation.——An annex to St. Vincent's Hospital, New York City, has been opened at Far Rockaway, about three minutes' walk from the station. Ocean breezes, ample rooms, well shaded grounds and trained nurses are mentioned as the attractions.——The Ladies' Deborah Nursery and Child's Protectory, New York city, has passed into the hands of a permanent receiver.

The proposed new hospital of Harlem, New York city, is likely to meet with much opposition by the owners of the site. It was to have been located on the east side of Lenox Avenue between 135th and 136th Streets, but the Equitable Life Insurance Society demur because the necessary condemnation proceedings will give them only the market price instead of the prospective value. The old Harlem Hospital has outgrown its capacity and a new institution in the upper section of the city proper is an absolute necessity. The Commissioners of Charities, who have taken in consultation the proper medical authorities, have authorized an expenditure of $300,000 upon the building alone and the cost of the land as calculated should not have been more than $200,000 at the extreme limit.

Washington.

The Chinese Apothecary.—A local Chinaman has made application for a license to sell medicine to his countrymen in the District.

Mandamus for the Board of Medical Supervisors.—The Board of Medical Supervisors for the District, in the opinion of Dr. Alderman, have been too slow in issuing a license for him to practice medicine and surgery in the District, therefore he applied to the courts to secure his rights, as he understands them. Judge Bradley issued a preëmptory writ of mandamus, requiring the Board of Examiners to show cause, etc.

Hospital for the Insane.—President McKinley has appointed Ex Surgeons General Francis M. Gunnell of the navy and John Moore of the army as members of the Board of Visitors to the Government Hospital (St. Elizabeth's) for the Insane.

The Contagious Hospital Site.—The Commissioners of the District have reported adversely the recommendation of Senator McMillan to locate the contagious hospital, recently appropriated for, in the grounds of the Washington Asylum. They base their adverse report on the bad hygienic conditions adjacent to the Asylum grounds. The eastern branch of the river, which passes directly back of it, is a cesspool and hotbed for disease breeding, it being practically an open sewer, receiving the sewage from a large portion of the District, where it is subsequently washed over the flats. This pestilential condition has more than once been reported by the surgeons in charge of the U. S. Naval Hospital and Marine Barracks and the surgeons in charge of the Government Asylum for the Insane, as being directly causative of a great deal of otherwise preventable disease in these institutions. The Medical Society and the Washington Board of Trade, through their health committees, have frequently pointed out the dangers of this locality. It is probable that the contagious diseases will eventually be treated in isolated buildings, to be erected in the grounds of two of the general public hospitals of the District.

Cincinnati.

Dr. Gillert I. Cullen is announced as associate editor of the *Medical Fortnightly* of St. Louis.

Dr. O. V. Limerick, who was jointly indicted with ex-Health Officer Dr. J. W. Prendergast on the charge of attempted blackmail of the Fraser Tablet Co., has been granted a new trial by the circuit court.

Dr. Robert Suttler has placed an order with Mundheuk, the sculptor, for a bust of the late Dr. E. Williams, who was the founder of the Ophthalmic Institute of Cincinnati.

The Tuberculous Patients and convalescing children of the Cincinnati Hospital have been removed to the branch hospital, which is located twelve miles from the city and in every way adapted for the care and treatment of these patients.

The Annual Meeting of the City Hospital medical staff resulted in the election of Dr. N. P. Dandridge president and Dr. J. C. Oliver secretary.

Dr. John K. Woods of Van Wert, Ohio, has been appointed chief surgeon of the Ohio division of the Jackson and Mackinaw Railway.

The Health Department has issued an order to the effect that hereafter all cattle added to the dairies supplying milk to the city must be tested with tuberculin, and those found diseased will be condemned.

At the meeting of the Academy of Medicine last week, Dr. James T. Whittaker read a paper entitled "Six Years with Tuberculin." He claimed that this remedy had proven to be the most valuable diagnostic agent and single remedy we have. The period of childhood was given as being the time of most frequent infection, and that of puberty of most frequent manifestations. Children who suffer with frequent or more or less continuous malaise, who feel more than others the confinement of the school room, who are said to be predisposed to phthisis, should be tested for some depot of tuberculosis. Children who live in an atmosphere of infection are almost necessarily subjects. Among the earliest signs mentioned usually are a peculiar odor of the breath, a red line on the gums, clubbed fingers, and local signs, as affection of the bones, joints, skin, testes, Fallopian tubes, adenitis. Scrofula is external tuberculosis. There is a pre-tubercular albuminuria, which is recognized by delicate tests, as by that of Spiegler. Cardiac palpitation and early dyspnea belong to the same toxemia. This albuminuria is not a nephritis, but is a toxic alteration of the albumin whereby it becomes more dialyzable. The Diazo reaction is less common and less reliable. The search for the bacillus in the blood in hectic fever and the other blood tests are really quite superfluous. Cough is most suspicious when it occurs in the morning and evening. Local depots excite no cough and there is no cough in acute miliary tuberculosis. The great contribution of modern times came with the discovery of the tubercle bacillus in the sputum. The use of the centrifuge, after fluidification of the sputum with soda or potash, shortens the examination and increases the value of the test. The pseudo-bacillus, the bacillus of leprosy, of syphilis, and of anemia were next differentiated. The discovery of elastic tissues was passed by because by this time there are physical signs. The importance of hemoptysis was remarked. It is not too sweeping an assertion to say that hemoptysis in perfect health means tuberculosis. Next followed the demonstration by inoculation of the guinea pig, which is certain but too slow to be of diagnostic value. In this way the clear effusions of pleurisy are determined to be tubercular in nearly three-fourths of the cases. The value of tuberculin in the diagnosis of the disease in cattle is universally accepted. According to the report of Salmon, thus far we have yet to meet the first case which reacted and did not show tuberculosis upon postmortem examination. The value of tuberculin was slow of recognition in man because of various objections, one, that reaction may set in in the absence of tuberculosis. These cases are now explained by the existence of concealed latent depots. The objection of Klemperer to the effect that reaction will occur with every deposit, even in latent cases, is really only confirmation of the value of the test. The most serious objection, that of Virchow, that tuberculin awakens tuberculosis from latent sources and disseminates the disease, an objection which was caught up and echoed on all sides, has been found to rest on erroneous premises. All the individuals who have had the most to do with the use of the remedy disclaim any danger of this kind. Thus Penzoldt, Wassermann, Prior, Springthorp and Klein all speak of the absolute safety of the remedy in proper use. The speaker had himself used tuberculin every day in hospital and private practice for six years, in now nearly one thousand cases, and had never seen any kind of evil result. Most of his use of the agent had been, of course, in the small therapeutic dose. But in the larger quantity necessary to secure the test reaction he had come to consider it the best possible and a perfectly safe means of diagnosis. Koch declared that his own individual experience in the early diagnosis of tuberculosis in man in more than one thousand cases shows its perfect safety and puts the diagnostic value of tuberculin in recognition of the disease in man on the same plane as in animals. The action of the remedy is ill understood, notwithstanding all the work that has been expended upon it. Introduced under the skin, it produces a general leucocytosis and fever, but tolerance is soon begotten to the use of the agent, so that individuals who react to a few milligrammes become finally insensitive to one hundred times this quantity. The knowledge of the existence of this tolerance to a poison was known in antiquity, and the principle is utilized in increasing the antitoxic properties of blood serum. The old tuberculin neutralized only the toxins of the tubercle bacillus, but in this method superficial processes are detached and discharged while reabsorption takes place in the interior of organs. Unfortunately, the effect is in no case final, because of the fact that the remedy has immunizing properties only against the toxins. With the new tuberculin there is higher promise because it immunizes against the tubercle bacilli themselves. "I have used the new tuberculin for about six weeks in twenty selected cases. The time is too soon to say anything more than that the dose is well borne by these patients, the signs of improvement are more continuous and the patients, most of them individuals under treatment with the old tuberculin, are better suited with the new."

THE PUBLIC SERVICES.

NOTICE.—An Army Medical Board will be in session at Washington City, D. C., during October, 1897, for the examination of candidates for appointment to the Medical Corps of the United States Army, to fill existing vacancies.

Persons desiring to present themselves for examination by the Board will make application to the Secretary of War, before September 1, 1897, for the necessary invitation, giving the date and place of birth, the place and State of permanent residence, the fact of American citizenship, the name of the medical college from which they were graduated, and a record of service in hospital, if any, from the authorities thereof. The application should be accompanied by certificates based on personal acquaintance, from at least two reputable persons, as to his citizenship, character and habits. The candidate must be between 22 and 29 years of age, and a graduate from a Regular Medical College, as evidence of which, his Diploma must be submitted to the Board.

Successful candidates at the *coming* examination will be given a course of instruction at the next session of the Army Medical School, beginning November 1, 1897.

Further information regarding the examinations may be obtained by addressing the Surgeon-General, U. S. Army, Washington, D. C.

George M. Sternberg,
Surgeon-General, U. S. Army.

Army Changes. Official List of changes in the stations and duties of officers serving in the Medical Department, U. S. Army, from June 5 to 11, 1897.

Capt. Robert R. Ball, Asst. Surgeon, leave of absence granted is extended two months.

Capt. Charles M. Gandy, Asst. Surgeon, now on duty at Washington Bks., D. C., will report in person, on July 1, 1897, to the governor of the Soldiers' Home near Washington, D. C., for temporary duty during the absence on leave of Col. William H. Forwood, Asst. Surgeon-General, and upon the return of that officer will rejoin his proper station.

Navy Changes. Changes in the Medical Corps of the U. S. Navy for the two weeks ending July 3, 1897.

P. A. Surgeon G. B. Wilson, detached from the "Yantic," ordered home and granted two months' leave.

Asst. Surgeon J. F. Leys, detached from the "Vermont" July 6 and ordered to the "Helena" July 7.

Asst. Surgeon C. E. Riggs, ordered to the "Vermont" July 6.

PAMPHLETS RECEIVED.

ORIGINAL ARTICLES.

SERO-DIAGNOSIS IN TYPHOID FEVER.

Presented in the Section on Practice of Medicine, at the Forty-eighth Annual Meeting of the American Medical Association held at Philadelphia, Pa., June 1-4, 1897.

BY WYATT JOHNSTON, M.D.
MONTREAL, QUE.

By his admirable summary, covering so thoroughly the general subject, Professor Welch has made much simpler the work of those who are to speak upon special divisions of the subject. In speaking of practical results I shall confine myself chiefly to my personal experience because it is with regard to that that I can speak most positively and which I feel most certain about. But I think where the results of one observer differ from those of another in this test one should be very careful in comparing the two, because very slight differences in technique, or interpretation of the phenomena observed will give a very different percentage in results.

My own experience consists so far in the examinations of somewhat over 600 bloods, of which more than half were from cases of typhoid fever. In these examinations and in my work I have been assisted very much by Dr. MacTaggart, of Montreal, resident pathologist of the General Hospital. Before covering the ground which Professor Welch has indicated as being a suitable field for discussion I might point out one or two directions in which the study of this reaction may be profitable aside from the question of the diagnosis of typhoid fever. There are other diseases which will give the reaction, cholera for instance, and, it is said, Malta fever and the bubonic plague. But both of these are rare diseases with which we have little to do. It seems to me that some other common diseases may give a diagnosis in this manner. With reference to typhoid, other applications of the test, such as the identification of doubtful cultures isolated from suspected water or suspected stools, might receive more study than they have. It would be foreign to the discussion to go into this subject, but some of the results of the preliminary studies which I have made in this direction have been extremely interesting, and very encouraging as showing a possible future for applying the test for the identification of the typhoid bacilli in suspected water, etc. We tried to utilize the clumping as a means of isolating the typhoid bacilli from mixed liquid cultures, and when one acts with media artificially infected with typhoid and colon bacilli the results are quite striking. One can produce clumping in the mixed bouillon of typhoid bacilli and colon bacilli, and one can filter this very much clumped culture through a filter of sand so that the typhoid will remain in the sand while the colon runs through the sediment. This can be seen very nicely by using this differential test on the sand and filter. The typhoid very largely remains in the sand, and the filtrate consists largely of colon bacilli. I have endeavored to apply this more in routine laboratory work, but have not yet succeeded in getting a definite practical method for routine use. This isolation might be of more value if combined with some other method.

Another experiment was to inoculate with a culture, and test for typhoid in the animals after about one week. In some cases I was able to obtain the reaction where the quantity of the typhoid material originally introduced was very small, represented by one part of bouillon culture to four millions of water, containing eleven thousand bacteria to the cubic centimeter. These experiments, however, I do not think are by any means as severe a test as one would find in natural unintentional infection of water, for where you artificially put in typhoid it is relatively easy to get at it again. I mention this simply as a field of possible utility.

With reference to the application of the method to the diagnosis of disease by using pure cultures, the field of application seems to have been transformed by advanced steps. Prior to Widal's discovery the impression was general, and I shared it, that this was an exceedingly complicated subject and very difficult to take up. The methods of Pfeiffer certainly did not sound easy. Widal, I think, has introduced marvelous clearness into the method. The whole thing became clear and comprehensible to the ordinary mortal, and has been largely carried out since. It was thought to be a bedside or clinical reaction, but subsequent events have shown that while it may answer well as a clinical test, perhaps the best results can be obtained in laboratories, and sending of material taken for diagnostic purposes to the laboratories to be examined there, is the best procedure.

With reference to the general application of the method, my own small share in the matter has been in the direction of trying to apply the principle of what I may call wholesale-public-health diagnosis, as introduced by Professor Biggs and Dr. Park. The object was to reduce to the minimum the trouble of the technique which one would expect of a person who had charge of a case, and transfer that, as much as possible, to the laboratory; so I made use of the fact which Widal had established, that drying of the blood did not interfere with the reaction, and applied it to the use of dried blood for the test. Whether this is the simplest way for transmitting material for examination depends largely upon the conditions of the case. As bacteriologist of the Province of Quebec, which comprises about two-hundred square miles, much of it sparsely settled, I think the method has distinct advantages. We have seen cases from Murray Bay, where the doctors are prompt in sending cultures. They send them on paper. We find that a great assistance in our work. I do not say that it is the method which should be used in hospital practice or city practice where the facilities for transmission are greater. It is a very simple thing to send the dried blood by post, and in our work we use the postal facilities very largely. So that, as to the method to be employed, I think Professor Welch has stated the matter extremely well, that it should be as simple as possible, but we must have an accurate technique. The attention to the technique has been, I think, very largely in the direction of quantitative estimation. The dried blood method at first did not seem to offer a promising field for quantitative estimation, and I remember feeling rather discouraged because other people were getting quantitative results and I could not. However, by the use of the hemometer, testing the hemoglobin by the ordinary coloring method in the solution of dried blood, one would get results corresponding very closely to what he would get in a control drop of blood which was not allowed to dry. Of course the longer the drying was continued the less accurate the results were. But I found that by this dilution I was not able to diagnosticate cases which I could diagnosticate without the accurate estimation of the dilution. A little practice will enable one to get a distinct reaction with a high degree of dilution. I do not say that it gives as good scientific results, but after using both methods I found that I could get just as good results without the dilution as with high dilution. But instead of the dilution, we used a special kind of culture, and I found there was a difference in this respect between serum and a solution of the entire blood. I think that is a point of some importance, so that what I say of blood solution may not hold true of serum. Blood solution appears to be more liable to give clumping, a false clumping, than serum. This is especially the case with typhoid cultures where the movement is very active, and for this reason in using dried blood it is better to get cultures where the motility is gentle. There is not much motility where we use old cultures. We found that out by accident. At first we used old cultures and got good results. It was only when we changed cultures that we got bad results, and on returning to the old method we found out what was the cause of success.

The question of the alkalinity of the culture is, I think, one of considerable importance, and one to which little reference has been made. The alkalinity has a marked effect on the clumping. A slightly acid medium may give no clumping, but by rendering it slightly alkaline clumping will again take place. The bouillon in which the culture is made seems to exercise some influence. Recently we found an excessive amount of spontaneous clumping taking place in our cultures and we were able to trace it apparently to the fact that the laboratory bouillon was made more alkaline than formerly; it was strongly alkaline instead of slightly alkaline. A culture which gives a very heavy growth, which does not work well with a bouillon of twenty-four hours, does not work well with the dried blood method, although it may with the serum. And if there is any deposit with the dried blood method in twenty-four hours, it does not work well so that one can tell, if he is using the culture every day, whether it is in good condition or not. It is important to get the bouillon in a proper state of alkalinity, and my object has been to get cultures into such condition that with this method they will not react to other bloods and will act decidedly to typhoid bloods. Although no positively accurate method may be obtained, yet one may get a method which is qualitative and reliable for the greater percentage of cases.

With reference to quantitative estimation, I think the variations produced by the condition of the culture and the alkalinity of the medium may have an influence in determining the quantitative result. There must be a fixed basis for the quantitative result and if this is going to react differently with different cultures there will be a shifting base.

With reference to the B. coli reaction, referred to by Dr. Welch, I find that also of considerable use in diagnosis in doubtful cases, where there are symptoms like typhoid but no reaction, or where there was a doubtful reaction blood. Such bloods I found generally to give a very decided reaction with the colon bacillus. This I interpreted to be due to B. coli inflammation, and it seems likely the colon bacillus in these cases is capable of producing a distinct infection which will give rise to symptoms very much like typhoid.

Definition of the reaction perhaps deserves more attention than it has received. What one man would call a reaction perhaps another man would say was not quite complete, so that uniformity of terms would be desirable. I believe that the coincident occurrence of the gradual cessation of motion and clumping is the characteristic feature; but if motion goes on and the clumping is not ultimately typical, that looks very much like pseudo-reaction. If there is clumping with incomplete loss of motion, it is perhaps to be regarded with suspicion; and I think in doubtful cases should not be considered so seriously as to upset the whole theory, borne out by such an enormous number of cases, as to the specific value of the reaction. Perhaps the selection of cases is something which deserves consideration, for one's results depend very largely upon whether he takes typical cases or doubtful cases; and I think a corroborative examination by means of bacteriologic tests in doubtful cases would give valuable additional evidence. Personally, I have never yet got a typical reaction in a case in which there was not strong ground for believing it was typhoid fever. I have had one case of typhoid fever in which the reaction was absent as far as I could make out, both by the dried blood method and the serum method, but that case was seen only in the later stage. It ended in recovery. Therefore we are not certain as to the nature of the disease. But possibly the reaction may be absent. It is not infrequently delayed into the late stage so that repeated examinations are necessary, and one can utilize for statistics only cases in which there have been abundant chances for observation and reexamination. I think these questions will be decided by the clinicians, not by the laboratory men, because so much depends upon the diagnosis of the case being accurately made.

DISCUSSION.

DR. N. S. DAVIS, JR., Chicago—This question of serum test has been one of great interest to me the last year, and fortunately soon after Widal's paper first became generally known I succeeded in interesting our resident physician, Dr. Miller, in making the examination in all typhoid fever cases which entered the hospital the last winter. He has carefully carried out the various methods, and the conclusions he has reached correspond very closely with those given by Dr. Cabot in his general summary. For example, he found in about 90 per cent. of the cases of genuine typhoid fever a positive reaction; in 6 per cent., of the cases he has found a partial reaction, not a perfectly positive one; in 3 per cent. there was no reaction whatever.

I remember one case under my observation a few weeks in which the febrile symptoms were so mild that we would scarcely have regarded it as a case of typhoid fever. There occurred, however, after the patient had been in the hospital four or five days characteristic typhoid stools. The reaction had been obtained in a very pronounced manner immediately upon the patient entering the hospital, which was on the third or fourth day of his illness. The course of the disease in that case was short, lasting only about two weeks. In other instances the reaction was not obtained until late in the disease. Of the cases examined not of typhoid fever, Dr. Miller found the reaction in 2.5 per cent. In part of these cases there was a history of prior typhoid fever, but not in all of them. It is evident, therefore, that while this reaction is very frequently present in typhoid fever, it is not an absolutely constant occurrence.

I feel inclined to criticise the tendency to call the reaction the typhoid fever test. Would it not be better to call it a symptom of typhoid fever? We have other symptoms of typhoid fever upon which we have relied in times past very largely in making the differential diagnosis where diagnosis was difficult, for example the occurrence of rose spots. Yet we know that rose spots occur occasionally in other diseases than typhoid fever. We know they do not occur in all cases of typhoid fever. Yet when we find rose spots in connection with other symptoms we make our diagnosis. We rely upon the *tout ensemble* rather than upon the individual symptoms. Therefore, would it not be better to regard the serum reaction as a symptom of typhoid fever rather than as a test, and take it only in connection with other symptoms, and not look upon it so exclusively, as some seem inclined to do, as a test pure and simple for typhoid fever?

Dr. H. A. **West**, Galveston, Texas—I wish to make one remark with regard to the importance of this test in sections of the country from which I come. It appears to me that it may be the possible means of settling some vexed questions in my section of the country with regard to the diagnosis of fevers. While in my own mind I have been satisfied as to the extensive prevalence of typhoid fever throughout Texas, and believe that the continued fevers which fail to yield to the salts of cinchona are typhoid fever, yet there is a division of opinion and the question is far from being settled. There is a class of practitioners who do not regard this continued fever as typhoid. They do not see the eruption; they do not find the ordinary classical symptoms of typhoid fever; they call it slow fever, catarrhal fever, simple continued fever, thermic fever, etc. There is another class of practitioners who call them cases of continued malarial fever. While they acknowledge the fact that they last three or four weeks, sometimes six or eight weeks, in spite of daily doses of 20 to 40 grains of quinin given during that period, still it is claimed that they are cases of malarial fever. The question came up at the State Association, and I regard it as one of the most important questions before the South or the country at large. From what I have heard this evening, I do think this method may be the means of settling that vexed question. I propose to carry it out to the extent of my ability, but I may say that the cases which I see in Galveston are classical typhoid fever with eruption, and running the course which typhoid fever runs the world over.

Dr. J. B. **Herrick**, Chicago—I will mention some of the results obtained in about one hundred cases by Dr. George H. Weaver in the laboratory of Rush Medical College. In general his results have been confirmatory of those we have listened to today, but in two cases, shown postmortem to be typhoid, the blood examination during life and after death was negative. Now it may be a peculiar coincidence that in these cases there was also tuberculosis. One patient, an adult negro, under my own observation, died of typhoid fever as nearly as we can judge, in the fourth week, and postmortem we found typical healing typhoid but also a tubercular gland opening into a vein serving to explain distinct tubercular foci. In the second case, not under my own observation, a somewhat similar finding was made. This, I say, may be a coincidence, but it opens up the question whether this serum reaction will be modified by mixed or secondary infection. I believe other observers have reported on a few cases of mixed infection where the reaction has been positive.

RELAPSES IN TYPHOID FEVER.

Presented in the Section on Practice of Medicine, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1–4, 1897.

BY WILLIAM OSLER, M.D.
BALTIMORE, MD.

One of the most distressing incidents which we may meet in typhoid fever is the occurrence of a relapse after we have guided the case safely to convalescence. The temperature has become normal, the patient is happy and hungry, the relatives contented, the doctor congratulates himself that he has cured a case of typhoid fever, and then comes the relapse and the tempest of the soul, so to speak. In the first place it is always a source of congratulation to the doctor that he is not personally responsible for the relapse. The condition under which relapse occurs is not, I think, in the large majority of cases within the control of the physician. Errors in diet are in some instances held responsible for it, but only in a very limited number of cases can the diet be held to be definitely responsible.

It is important in the first place to define accurately what a relapse is. I think the term should be limited exclusively to reinfection after a distinct and definite period of apyrexia. It is quite true that that definition does not include a certain number of cases which have been termed the intercurrent relapse, and we have a certain number of cases in which the temperature falls not quite to normal, say to 100 degrees F. or the morning temperature to 99.5 degrees, while for three or four days there is a distinct lull and then a recurrence of the symptoms. One is often in doubt whether such a case should be positively called a relapse or not; but such cases should be grouped as intercurrent relapses and not as true relapses. The occurrence of a relapse is an indication that immunity in typhoid fever is slowly acquired, and not fully acquired when apyrexia is reached.

The sources of the reinfection are as yet unknown, just as are the conditions under which relapse develops; but of the possible sources of reinfection we may mention the lingering of the typhoid bacilli in the mucous membrane and in the adenoid tissues of the intestines. We have been told today by Dr. Richardson, that even after a considerable period of apyrexia typhoid bacilli have been found in the stools. Then it is possible that the source is in the mesenteric glands and the spleen—in the latter region we know that typhoid bacilli remain for a very considerable length of time after convalescence. Chiari recently made an interesting suggestion that the typhoid bacilli remain in the gall bladder, persisting after a long period of time, not only for weeks but even for months, and that the organisms in the gall bladder may be the source of reinfection. He has found typhoid bacilli in the gall bladder in nineteen out of twenty-three cases, a much larger percentage than has been met with by other observers. But the persistence of the typhoid bacilli in the bile passages is well recognized, and he suggests that the taking of an extra amount of food and gastric disturbance may be associated with the passage of a large number of these bacilli from the gall bladder into the intestines.

The evidence of relapse is very different in different series of cases. Up to Aug. 5, 1896, 500 cases of typhoid fever were treated in the wards of Johns Hopkins Hospital and forty cases had relapsed, or 8 per cent. That is the same percentage as is given by Liebermeister in about the same number of cases. It is a very much larger percentage than that given by Murchison in a larger series of cases—in two or three thousand cases there were only 3 per cent. of relapses. Other percentages run up as high as 20, but older observations, and even more recent ones, show that the percentage of relapses varies very much indeed. The relapses may not be single but double, now and then triple, and a few cases have been reported in which four or five relapses occurred. We have only had a few cases in which two relapses occurred, none in which there were three.

As illustrating the extraordinary length to which a case of typhoid may drag itself with only two relapses, I may mention a case which was admitted in October, 1893. The patient was a doctor, admitted to a private ward with well characterized typhoid fever. The temperature became normal on the forty-first day. There was then complete apyrexia for twenty-three days and the patient had arranged with relatives to be taken home. But fever developed and persisted forty-one days, the temperature reaching from 104 to 105 degrees F. Then there was a period of complete apyrexia for forty-two days, six full weeks without fever. Then there was fever for fourteen days, without rose spots, it is true, but with furred tongue and moderately high fever and with some abdominal distension. So that altogether the original attack with the two relapses covered a period of very nearly six months.

The mode of onset of the relapse is interesting. It is not always, as stated in most works, exactly like the original attack—a stepping up of the temperature each day. It may, in fact, begin abruptly, as in the case which I have just mentioned. The onset of the first relapse was with a series of chills, and a maximum temperature of 105.5 degrees was reached within twenty-four hours of the beginning of the fever. Those cases are not very uncommon. In other instances the relapse is the exact counterpart of the primary attack, the temperature rising gradually, a degree or a degree and a half daily.

Another question has been raised to which I would like to refer, namely, whether the Brand treatment has anything to do with the increased number of relapses. Our percentage is, as you have noticed, not very high, and I do not think one can state that hydrotherapy has any influence in promoting relapses. There are many series of cases with a larger proportion of relapses in which hydrotherapy had not been carried out. Indeed, in certain series in which the relapses have been up to 15 or 20 per cent., the ordidary expectant method of treatment, or perhaps more correctly, the various medicinal plans of treatment have been carried out.

FURTHER REPORT OF CASES TREATED WITH ANTI-TUBERCLE SERUM.

Read in the Section on Practice of Medicine at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY PAUL PAQUIN, M.D.

ST. LOUIS, MO.

In presenting this report to the American Medical Association I am not mindless of the many objections which have been presented against sero-therapy in this disease, and of the numerous criticisms which have been passed upon it, and of the feeling of apprehension and doubt which still pervades the minds of many of the profession. I am fully aware that experimental tuberculosis in small animals has failed to accomplish to the degree expected, the kind of so-called cure, hoped for. Nevertheless, I again take the liberty of presenting a report of cases treated with serum, with the results obtained since the last months of 1894 to this date. Naturally, I must leave out a large number of cases of which the reports are incomplete, or otherwise unsatisfactory for the reason, on the one hand, that some physicians did not keep the proper records, and on the other, there was in certain cases some doubt of the nature of the disease and of the results obtained. The cases reported here are such as I know had tuberculosis, and, I feel convinced, have experienced the results I shall mention.

In January, 1895, I presented to the St. Louis Medical Society a report of the results obtained in twenty-two St. Louis City Hospital patients, who had been treated exclusively with serum for three months. The good results in certain classes of patients were so uniform that the presentation of the matter was warranted at the time. The experiments were interrupted there by change of administration and the patients scattering I was able to keep track of only three of those improved, all of whom are still living and back at work apparently well, although I do not yet use the designation cured.

A second report of entirely new cases was made to the St. Louis Medical Society in March, 1896, and included the recovery of two *acute* cases of pulmonary tuberculosis, who had been in the care of three leading physicians of Missouri, who had given as their opinion that there was no hope. It also included the recovery of fourteen cases of chronic pulmonary tuberculosis. In that report I made the following statement: "That of 100 cases treated in a period of eighteen months, the following results obtained: In the first and second stage, as understood in general practice, 14 recovered; in the second stage, improved or checked or still improving at the time, 26; among these 26, 12 seemed to have really recovered, although the time had not been long enough to warrant positive assurance; there had disappeared from observation, in all stages, 35; died during treatment, begun at the third and fourth stages, including 10 moribunds who insisted on trying the treatment, 25. In the same year, Dr. Hayden of Evansville, Ind., reported 4 cases of tuberculosis; all improved and 2 apparently recovered. Besides these. Drs. L. L. Shropshire, San Antonio, Texas; Dr. William Miller, Boerne, Texas; Dr. Hoell Tyler, Mentone, Cal.; Dr. H. S. Lewis, New Orleans, La.; Dr. E. L. Mitchell, Carbondale, Ill.; Dr. J. M. Allen, Liberty, Mo.; Dr. A. G. Deardorff, San Francisco, Cal.; Dr. J. L. Wiggins, E. St. Louis, Ill.; Dr. J. L. Dunwoody, Cripple Creek, Colo.; Dr. W. H. Prioleau, Summerville, S. C., reported the recovery of ever twenty-five cases and marked improvement in over one hundred, while at least seventy-five physicians have reported improvements, of various degrees, in over one hundred cases impossible to record, most of them hopeless from the beginning.

In September, 1896, I presented a report to the Virginia State Medical Society, of a total of 226 cases of tuberculosis. I quote from this paper:

Class.	Pulmonary Tuberculosis.	No. of Cases.
1.	Destructive broncho-pneumonia with cavities	37
2.	Destructive broncho-pneumonia without recognizable cavities	66
3.	With diffuse febrile pneumonia with or without a destructive process	19
4.	With diffuse non-febrile broncho-pneumonia with or with- [illegible]	19
5.	W[illegible] le broncho-pneumonia	[illegible]
6.	W[illegible] stic broncho-pneumonia	[illegible]
	Diagnosis not reported clear enough for classification	[illegible]
	Hip-joint tuberculosis	[illegible]
	Laryngeal tuberculosis	2
	Ovarian tuberculosis	1
		226

In every one of these cases the diagnosis had been verified microscopically. During the treatment of these 226 cases the following conditions obtained:

Effect of serum on fever: 60 subsided, 56 reduced, 26 stationary, 84 not recorded.

Effect of serum on night sweats: 69 subsided, 17 unchanged, 140 not recorded.

Result of serum on weight: 125 increased, 15 unchanged, 27 decreased, 59 not recorded.

Result of serum on strength: 154 increased, 9 unchanged, 24 decreased, 39 not recorded.

Result of serum on appetite: 114 increased, 15 unchanged, 31 decreased, 66 not recorded.

Result of serum on local signs: 40 disappeared, 58 mitigated, 28 unchanged, 100 not recorded.

Result of serum on tub. bacilli: 40 disappeared, 103 reduced, 7 altered, 76 not recorded.

Result of serum on general well being, exclusive of the 40 recoveries: 145 improved; 9 unchanged, 32 not recorded.

Number of recoveries that seemed complete and permanent	40
Number of apparent recoveries with existing lesions (cavities) in statu quo	3
Number of improved capable of performing usual duties	41
Number of improved to a lesser degree	69
Number of deaths reported	32
Number of cases disappeared from observation or under various treatments	41
	226

As to the pulmonary cases, the extent, stage and importance of the conditions at the beginning of were as follows:

In Class	1	there	were	20	cases in	advanced	stage;	3	in early	stage
“	2	“	“	33	“	“	“	6	“	“
“	3	“	“	12	“	“	“	0	“	“
“	4	“	“	9	“	“	“	0	“	“
“	5	“	“	12	“	“	“	3	“	“
“	6	“	“	7	“	“	“	1	“	“
				93				13		

Not classified accurately enough for satisfactory description of the stage 120

I beg to say today that those cases reported as having recovered, dating back from one to three years, are still living and apparently well. None of these cases recorded as having improved greatly have succumbed yet, but some of those reported as having up to that time remained unchanged or mitigated or slightly improved, have since died. I have been unable to get an absolute record as to the number of these, although we are using a method of tabulation and clinical report chart which we send out to physicians using the serum. It seems that not one of the cases reported by doctors as having recovered, or in which the disease seemed to have been arrested permanently, have had a relapse, so far, although most of them remain in an unfavorable climate where the disease originated, as in St. Louis, for instance.

I beg now to present a report of 67 cases, which were not included in the foregoing, and which have been treated in the last year, and purposely recorded since the last meeting of the AMERICAN MEDICAL ASSOCIATION, concerning which I have direct information.

Total number of cases 67.

Effect on fever: 17 subsided, 22 reduced, 5 increased, 23 not recorded.

Effect on night sweats: 26 subsided, 4 unchanged, 27 diminished, 10 not recorded.

Effect on weight: 40 increased, 11 unchanged, 4 decreased, 12 not recorded.

Effect on strength: 34 increased, 10 unchanged, 4 decreased, 19 not recorded.

Effect on appetite: 34 increased, 10 unchanged, 4 decreased, 19 not recorded.

Effect on local signs: 17 disappeared, 22 mitigated, 27 not recorded.

Effect on tubercle bacilli, 17 disappeared, 35 reduced, 15 not recorded.

Number of recoveries that seem complete at present	17
Number of improvements to a considerable degree	35
Improvements to a lesser degree	11
Deaths	4

Thus the grand total of cases recorded above properly enough for reliable report is, not including the various doctors' reports herein mentioned 293

Of these, have recovered	57
Apparent recoveries with lesions in statu quo	3
Improved capable to perform again usual duties	76
Improved to a lesser degree	80
Deaths reported (probably some not known)	36
Cases disappeared from observation	41
	293

This report does not include the numerous cases in which serum was tried in moribunds or in more favorable cases for too short a time. Nor does it include a number of cases improved in the last few months by using serum by rectal injection.

In concluding this report, I wish to say that too much is expected of sero-therapy in tuberculosis, or of any treatment for that matter. It can never be possible to arrest consumption when the tissues are so destroyed and their generative energies so enfeebled that they are beyond the power of stimulation. It is only in the early stages that one may expect the best results (and in the early stages it is a most efficacious remedy). One great trouble we have to deal with is mixed infection and this can be reached only by the use of antitoxins prepared specially for the germs producing the complications, assisted occasionally by other measures. Tubercle antitoxin can not act directly against microbic complications. Furthermore it should not be forgotten that the destructive process of tuberculosis is so great, so comprehensive, that no means of wise special or general treatment should be spared to assist sero-therapy or any other special treatment in the work of repair. Most of them were cases of an experimental character. The cases which I have submitted here have been treated almost exclusively by the use of serum.

I am fully convinced that no one is warranted today in proclaiming the absolute and exclusive curative properties of an exclusive specific alone in tuberculosis of all kinds. Every case must be treated on its merits, considering in each the symptoms, lesions, predispositions, inherited conditions and the various susceptibilities present. Sero-therapy is nature's remedy and offers the greatest assurance of benefit in the subjugation of the specific cause or causes, but in most cases, as just stated, it should be supported in its splendid work by such hygienic, dietetic and medicinal measures as are considered wise for each individual case.

THE CAUSE AND MECHANICAL TREATMENT OF SUBLUXATION OF THE KNEE-JOINT.

Read at the Third Annual Meeting of the American Academy of Railway Surgeons held at Chicago, Sept. 23, 24 and 25, 1896.

BY S. L. McCURDY, M.D.
SURGEON TO THE PENNSYLVANIA CENTRAL RAILWAY.
PITTSBURG, PA.

In order that the treatment of subluxation of the knee-joint may be properly carried out its cause must be thoroughly understood.

Subluxation of this joint is an under-dislocation of the head of the tibia back of, or posterior to, the condyles of the femur. Such a deformity does not exist as a result of chronic disease when the femur is kept parallel with the tibia, during tubercular, synovial, traumatic, gonorrheal and other inflammatory diseases in and about the knee-joint. It can only result from direct violence and from faulty position during the course of treatment.

The series of experiments has been carried out to determine the relative power of the flexor and extensor muscles of the leg, as well as to determine at what angle, in flexion, the flexor muscles equal the extensors in power. We must remember that extension of the leg is limited to a parallelism with the thigh, and that flexion is only limited by the resistance of the calf with the thigh muscles, or through an arc of 90 degrees. In extension the flexors and extensors are antagonists, and oppose each other with equal advantage, so far as the position of the bones themselves are concerned, because they both have direct action. The advantage, however, is in favor of the extensors, because they are always more powerful. When the leg is flexed the extensors lose their power of direct action and act over a pulley. This pulley is formed by the action of the quadriceps extensor femoris, patella and ligamentum patellæ over the condyles of the femur. As the leg is flexed the extensors lose power and the flexors gain. In order to determine the power of these sets of muscles and to more particularly determine at what angle of flexion the flexors equal the extensors, experiments have been carried out.

Without giving in detail the various experiments which were made upon different individuals, it was found that the extensor muscles upon an average had a resistance of thirty-two pounds, and the flexors twenty-four pounds and that at an angle of about 35 degrees the resistance of the extensors was reduced to twenty-four pounds. This shows that the extensors and flexors have equal power when the leg is flexed to an angle of 35 degrees. A slight variation from the above is found in different individuals.

The experiments were carried out by the use of a goniometer, a pair of spring scales, and four hooks on the jam of a door, one on either side opposite the knee and the other two below these near the floor. To test the extensors, a tape is secured to the hook in front of the knee and thrown around the knee above the joint. The scale is hooked to the hook back of the foot, and another tape is thrown over the ankle and the free ends passed through the ring of the scale. With the leg in extreme extension the tapes are drawn through the ring of the scales. The scales will first register the extreme power of the extensors, but as it is drawn back to about 10 degrees it requires less force to make flexion, hence, a reduction on the scale dial.

To test the flexors, the scales are placed in front of the foot and the knee secured from the hook immediately back of it.

It is quite customary to treat the diseased conditions of the knee-joint in flexion, the degree of flexion being determined by the attending surgeon. Some reasons given for this are that it places the leg in a better position for use during after years, or it is more comfortable to the patient, etc. All of the reasons given are fallacious and founded upon anything but sound reasoning.

In the case of traumatic and other forms of synovitis it is probably true that a greater area of synovial surface is included between the heads of the bone and semilunar cartilage. Such a reduction in actual surface pressed upon could not diminish the pressure, but would place the leg in a less secure position and thus increase muscular spasm and as a result increase intra-articular pressure.

It must be remembered that all muscles which pass over, or the tendons of which pass over or control the action of a joint in inflammation, are in a state of spasmodic contraction. This increased action on the part of the muscles is an effort on the part of nature to protect the sensitive joint. The deformity which follows is in the direction of the most powerful muscles, or sets of muscles.

In hip-joint disease it is flexion, adduction, or abduction. In tarsal disease it is valgus, varus, flexion, extension, etc. In knee-joint disease it may remain normal, as it generally does in diseases of the shoulder or wrist, so long as the leg is kept in a position favoring this. Just as soon, however, as the flexors have a greater power than the extensors we have an increase of flexion.

As a result of my experiments an approximate estimate of the muscular power showed that the flexion at an angle of 45 to 50 degrees, the flexors had absolute control of the leg. This will admit of two things, an increase of flexion and a tendency of the head of the tibia to glide further back under the condyles. This is not only correct theoretically, but it is borne out clinically and has no doubt been observed by many of my hearers.

I have thus dwelt at length on the cause of the condition under consideration in order that the treatment might be preventive rather than that we be called upon to correct the deformity after its existence.

The treatment of subluxations may be summed up briefly as follows:

It must first be determined whether true or false ankylosis exists, whether the dislocation is partial or complete. In true ankylosis a complete section of the bone must be made either by the use of chisels or saw, and if the relationship of the bones can not be restored without it, a wedge-shaped section should be made, the bones brought together and or otherwise secured.

In cases of ligamentous or false ankylosis with a partial subluxation, *brisement forcé* with tenotomies of the hamstring tendons is generally sufficient. The most difficult cases to manage are those where the adhesions are more or less firm and a complete luxation of the bones exists.

Tenotomies of the tendons will free the lower portion of the head of the tibia, but great force does not as a rule restore the joint surfaces to a normal relationship. It is quite possible, after tenotomy, to bring the leg parallel with the thigh, but it will be found that the leg is upon a lower plane than the thigh. This is due to the fact that the head of the tibia does not slip down and forward upon the condyles, but instead the relationship of these bones are not disturbed.

Immediate reduction of subluxation of the knee-joint is prevented: 1. By the adherent patella and synovial membrane to the condyles. 2. By the impinging of the anterior portion of the head of the tibia against the condyles. In cases where the hamstrings are not cut this burrowing in of the bones upon each other is much greater, and an immediate reduction is less likely to be effected. Gradual and continuous leverage offer the best means for correcting the deformity mechanically. In this degree of deformity a rapid cure can not be promised. except by a radical operation.

A complete correction mechanically must not be attempted at the time of the practice of *brisement forcé*, but instead the leg should be carried forward to an angle that would permit a gradual correction of the subluxation. If plaster of Paris is used as a support, it should be reapplied every ten to fourteen days.

DISCUSSION.

Dr. Mayo—Dr. Gillette of St. Paul, in a number of cases, has broken up the adhesions by means of great force, using some form of mechanical apparatus in one sitting and without tenotomy. I have myself been afraid to apply this extreme degree of force, and, if the deformity is sufficiently great, much prefer to make an osteotomy of the femur after the method of Macewen; this, it appears to me, gives the best results with the least loss of time and danger. The mechanical apparatus of the doctor I believe would succeed better in the hands of the inventor than with the rest of us. In my experience I have seldom been able to succeed with another man's splint as well as does the inventor himself, and as a rule do better with the plaster of Paris cast.

Dr. Hawes—I wish to take exception to one statement in the paper; no mention is made of complete reduction of the subluxation at one sitting. I think the best result I ever had was where it was necessary for me to use force; I actually tore the skin in the popliteal parts. The splint I have been accustomed to use has two bars on the outside and one inside, extending from the inside of the thigh to the heel and outside to the heel and carrying the bandage around it all, behind the tibia. It seems to me I ought to get better results than I would with this splint.

THE DIAGNOSIS OF MALARIA.

BY ARTHUR R. EDWARDS, A.M., M.D.

Professor of Therapeutics, Northwestern University Medical School; Professor of Practice and Clinical Medicine, Northwestern University Woman's Medical School; Attending Physician to Cook County Hospital and St. Luke's Hospital; Pathologist to Wesley Hospital, Chicago.

The diagnosis of malaria, like its pathogenesis, has a scientific life of scarcely two decades. The subject has been roughly handled since an acquaintance with its microscopic diagnostic methods has reached the general profession from the laboratories of scientific biologists and clinicians. As in all newly developed methods, medical and otherwise, there is a tendency to swing from one extreme to the other. Great skepticism greeted Laveran's initial reports that certain parasitic elements existing in the blood of malarial patients and hitherto confused with pigment-bearing leucocytes, were the cause of malaria. The general skepticism of Laveran's colleagues is now superseded by equally universal credulity. While previously no parasites were admitted, now they are even confused with the constituents of the normal blood. Five years ago the existence of malaria in Chicago was denied, while today many vague diseases, especially obscure or obstinate fevers, are diagnosticated malaria.

I. DIAGNOSIS OF THE EXISTENCE OF MALARIA.

(*a.*) *Positive blood findings*, i. e., the detection of the plasmodium of malaria, establishes the fact o malaria, since malaria is always caused by the parasite, and again the organism is almost always found in malaria and in malaria only. A few microscopic examinations will convince the greatest skeptic. It must not be forgotten that, in certain instances, two diseases may occur simultaneously. We have seen malaria in conjunction with various ancient heart lesions, ulcerative endocarditis, pulmonary tuberculosis, chronic nephritis, although never with typhoid fever. These coincidences are, however, infrequent, and the presence of malaria plasmodium makes possible positive differentiation from other diseases, e. g., the frequent error of overlooking or misinterpreting an incipient pulmonary tuberculosis attended with chills. Atypical fevers, associated with chills and sweating, which have few or dubious local findings and are therefore difficult of diagnosis, can at least be differentiated from malaria; for example, analagous typhoid, septico-pyemia occulta, generalized miliary tuberculosis, febrile gastritis, cholecystitis suppurativa, central pneumonia, deep-seated sarcomatosis, ulcerative endocarditis, etc.

(*b.*) *Negative blood findings*, in suspected malaria, are not definitive from one examination. Not infrequently is more than one microscopic search necessary for the positive exclusion of malaria. While suggestive, then, a single negative finding is far from conclusive. The parasites may be indistinguishable in the first few days of the disease. In certain forms they swarm in internal organs, avoiding the peripheral circulation; and lastly, in chronic and recurrent types they are found with great difficulty. Sometimes visceral (splenic) puncture is needed for their detection.

(*c.*) *Fallacies.*—Certain deformities in the red blood corpuscles are often mistaken for plasmodia, *e.g.*, crenations, poikilocytosis and vacuole formation. Not only can the more intimate structure of the red blood discs retract, simulating plasmodia, but the exterior of the hemacyte is far more plastic than is commonly acknowledged, even to the extent of protruding pronounced pseudopodia-like processes. These are but too frequently mistaken for parasites, being found in very many instances of apparently otherwise normal blood. Vacuole formations are characterized by their sharp contour and high luster.

Melaniferous leucocytes are readily distinguishable from the plasmodia by their large nuclei and by their ameboid movement, always absent in adult parasites of equal size. Unstained spores may be confused with the blood plaques, which are, however, structureless and contain no pigment. An Austrian pediatrist lost a docentship for reporting as malaria cases whose blood preparations afterward proved to contain only blood plates and no plasmodia. Coagulation products have been confused with flagella. Many of the small dots seen in malaria which resemble micrococci and were mistaken for such by the earlier Italian observers are similar to those found in most anemias and described by Ehrlich as degenerative changes.

II. DIAGNOSTIC TECHNIQUE.

Complex methods of staining and counterstaining the parasite have been in vogue, but the simplest and most accurate is the direct examination of the freshly-drawn unstained blood, a method we have used with entire satisfaction for several years. In this procedure injury to the corpuscles and staining of the blood plaques are obviated.

The lobe of the ear is cleansed, pricked and a quite small drop is gently expressed. A clean cover glass is held in a pair of forceps to avoid the heat and moisture of the hand, and is carefully brought in contact with the top of the drop. The heat and moisture of the hand or rudely placing the cover against the drop favor imperfect spreading from precipitate drying of parts of the blood. Rubbing the slide well facilitates equable spreading of the blood. Examination is best made with an oil one-twelfth inch immersion lens, although Laveran used lenses of lower magnification. Permanent preparations are procured by allowing the covers to dry. to remain half hour in equal parts of absolute alcohol and ether and by painting with filtered eosin and methylene blue. The use of stains is not usually

M.S. Medical Colle

advisable, since they obscure the otherwise more brilliant microscopic findings, they act as protoplasmic poisons, abolishing both the ameboid movement of the parasite and the highly characteristic vibrations of its pigment, and finally, they stain the blood plates and coagulation products, thereby confusing the findings, particularly for the unwary clinician.

III. THE DIAGNOSIS OF THE TYPE OF MALARIA.

It is impossible to enter here into the detailed differential morphology of the malarial parasites. Blood examination, however, demonstrates not merely the fact of malaria but also its types, since the various clinical forms of the disease correspond to zoölogically distinct, immutable species of parasite. Determination of species embraces more than purely biologic interest; it declares also the prognosis as in the pernicious forms and designates the treatment, as arsenic in the tropical types. Councilman stated several years ago that in intermittent fever the parasite was seen within the red blood corpuscle, while in remittent fever or in malarial cachexia it was frequently seen without the same or in elongated forms and crescents. Crescents augur relapse. The presence of segmentation forms predict an imminent or incipient paroxysm. The alleged detection of plasmodium is often doubted by us, since it is not uncommon to hear practitioners state that they have found Laveran's organisms an error at least in species determination.

In general terms, the number of parasites found in the blood corresponds to the severity of the attack, although Antolisci, and others with him, believe the large spore-producing bodies remain largely in internal bodies.

Relative exceptions to this rule exist.

(*a.*) *Diagnosis of type from motility.*—In the ordinary tertian parasite there is lively ameboid movement in the young and middle-aged forms. In the quartan form there is slight movement in the young parasite. In the estivo-autumnal type it is variable, often very active.

(*b.*) *Diagnosis from pigment.*—In tertian malaria the pigment is pale and yellowish brown, is fine, and in the young forms is most active, or "swarming"; it accumulates toward the periphery of the parasite, as the pseudopodia protrude, but in the older forms it becomes central. The pigment is inversely proportional in amount to the ameboid movement, *i. e.*, the more pigment the less the ameboid movement.

In the quartan the pigment is coarse, being somewhat larger than in the tertian, irregular, with but little if any movement.

In the estivo-autumnal form the pigment is active, although some describe it as slight, at first fine, later coarse, even rodlike.

(*c.*) *Diagnosis from size.*—The tertian is as large as the red blood disc, even larger; the quartan not larger than the red corpuscle, while the tropical forms are much smaller, from 1-5 to ⅔ the size of the hemacyte.

(*d.*) *Protoplasm of the parasite.*—In the tertian it is pale and indistinct; in the quartan sharply outlined, and of a characteristically high index of refraction; in the autumnal type it is ringlike, very small, hyaline and difficult to detect.

(*e.*) *Morphologic alteration in the red blood cells.*—In the tertian the red blood cells hypertrophy and are rapidly and completely decolorized. In the quartan they are but little decolorized. may be darker than normal and are not essentially altered in size, although the corpuscles may become slightly smaller than normal. In the more pernicious types they are shrunken, become either darker, of "brassy" color, or completely decolorized, "shadowlike."

(*f.*) *Diagnosis from sporulation form.*—In the tertian the spores are more or less irregularly grouped, individually small, round, whose nucleolus is seldom seen in unstained specimens, numbering 15 to 20 or somewhat less. The segmenting forms are about the size of a red disc, and are of irregular form. The segmenting bodies are found in the peripheral blood rarely, or in small numbers only, except at the time of a paroxysm.

In quartan malaria the spores exist in the marguerite form, spores being individually long, with distinct nucleolus, 6 to 12 in number. The segmenting forms are smaller than a red blood corpuscle, of a rosette form, are found in equal numbers in the peripheral and visceral circulations, and may be detected in the apyretic interval as well as in the paroxysms. In the estivo-autumnal types the spores are irregularly formed or stellate, six to eight in number, possibly more, and segmentation occurs chiefly in internal organs.

(*g.*) *Diagnosis from crescents and flagella.*—The crescents are found only in the estivo-autumnal forms, and represent a very resistant form of the organism. They may exist for months at a time without fever or other symptoms. They may be converted into round bodies, from which flagellation is frequently observed. We have never seen crescents apart from extreme anemia. Persisting as they do we can scarcely consider them solely as degeneration forms; they impress us rather as resting stages.

Flagella may be found in any type, though not frequently in quartan fevers. They may be seen when quinin has been previously given, and have been considered by some as degenerative forms. They are but rarely seen in freshly shed blood, but we have seldom missed them when examining a specimen for a long period, *e.g.*, in clinic demonstrations.

IV. THE DIAGNOSIS OF INDIVIDUAL MALARIAL SYMPTOMS.

The diagnosis of individual or isolated cases is most intimately linked with the diagnosis by blood examination. Certain malarial symptoms are not only immediate sequences of the malarial infection, but are also most beautifully explained by the life cycle, life activity and metabolism of the organism.

The melanemia corresponds with the structural disintegration of the hemoglobin of the red blood cells and its diffusion through the blood plasma. The anemia is secondary to reduction of the hemoglobin and diminution of the number of red blood corpuscles; in other words, to morphologic hemodyscrasia. No leucocytosis is seen, save a transient apparent increase at the beginning of the paroxysm. The hemoglobin and red discs are destroyed in equal degree. The anemia is rapidly produced; in fact, corpuscular deglobulization is more rapid than in any other acute affection, and can be utilized to differentiate from pneumonia or typhoid fever.

Each paroxysm being the ripening of a new generation of parasites, the fever corresponds to their sporulation and a saturation of the blood with toxins liberated from the red blood cells. It is a chemic hemodyscrasia or, as Mannaberg aptly puts it, a "protozoan sepsis," analogous to that discharge into the blood stream of infective material observed in septicopyemia.

We fully comprehend any clinical form of fever, when we realize that the fever is a toxic manifestation and that as often as the parasites segment, fever occurs. Hence two generations of tertian parasites cause quotidian fever, also caused by three generations of quartan parasites of unequal age. Quotidian continued fever accompanied by splenic tumor, the diazo-reaction, and even roseolæ or slow pulse, may cause difficulty in diagnosis from typhoid fever, especially as typhoid may be attended with chills and sweats. The blood examination speedily differentiates and Widal's serum test for typhoid is of great aid. The splenic tumor and bone pains are explained by the phagocytic process in their substance, the hemoglobinuria, diarrhea, retinal and other hemorrhages by the toxemia, the cerebral symptoms, as coma, convulsions or bulbar symptoms, by aggregations of the parasite in the cerebral vessels with thrombosis.

Some special mention of the diagnosis of the estivo-autumnal form is timely since the disease may be imported from the South, and require prompt recognition. Personally we have seen two fatal and a third comatose case, the same number reported from Osler's clinic. The disease is acyclical, arrhythmic in sporulation; while quotidian in type, the paroxysms are of long duration, lasting nineteen to twenty-four hours and frequently overlapping each other with irregular or continuous fever as a sequence. Often chills and chilly sensations are lacking, the rise of fever is gradual instead of sudden and the febrile solution is also gradual. There is greater tendency to retardation or anticipation of the paroxysm than in quartan or tertian types. Profound anemia and cachexia are common, fever may be lacking, relapses are imminent, as long as crescents are found, indeed after they have disappeared and finally spontaneous recovery is infrequent.

V. THE DIAGNOSIS E JUVANTIBUS.

The therapeutic diagnosis, despite the fact that quinin is a specific remedy, is subject to certain errors. First, many fugitive febrile diseases disappear under the use of quinin, which run their short course with equal celerity under other treatment or with no treatment at all. Hence not all is malaria which quinin seems to cure. A blood diagnosis must precede and succeed the therapeutic test.

Second, malaria manifests a certain tendency toward spontaneous recovery. The disease untreated follows a cycle: 1, a gradual increase in the intensity of the paroxysm; 2, a period of oscillation; 3, spontaneous recovery; 4, a relapse in one or two weeks. Then the same rhythm of symptoms is followed. Not infrequently in hospital practice when we give a placebo that we may study the plasmodium, the disease disappears without therapeutic interference. Hygiene, change of habitation, rest in bed and lack of reinfection favor self-limitation. While the fever is a symptom of malarial infection, it is per se a conservative process, killing the parasites. Indeed if all parasites are of the same age, a catastrophe ensues, and the disease is instantaneously cured by the fever. Many of the germs remain sterile. Spontaneous recovery is most common in tertian types and least frequent in the estivo-autumnal variety. The process of phagocytosis, while not yet completely understood, undoubtedly plays an important rôle in spontaneous recovery. The multinuclear neutrophile leucocytes have the greatest phagocytic action and the process is almost always noticed when the flagellate forms abound. Phagocytosis is most marked during the paroxysm and lasts eight to twelve hours. It is consummated by the macrophages of the spleen, liver and bones and to a lesser extent by the endothelial cells in various organs, *e. g.*, the cerebral vessels and by the leucocytes. The slow current of the hepatic vessels, and their large caliber aid the process.

The use of quinin.—The drug does not greatly impress the endoglobular parasite, shielded as it is within the protoplasm of its host, the red blood cells. Coming in access with the free spores in the plasma, it speedily destroys them, and the disease may be extinguished at one dose, as it were, if the parasites are of but one generation. Highly specific in the tertian and quartan types, it is resisted more effectual by the estivo-autumnal form. Most authors state that the specific action of quinin is manifest even in this form, unless the case is far advanced before treatment is begun. We have seen the estivo-autumnal resist sixty grains of quinin per diem for two weeks, and then to react but slightly to the drug.

Regarding our endogenous malaria, the benignant tertian variety, the therapeutic diagnosis can be quickly made. Twenty to thirty grains should at once destroy at least the fever type and, repeated, should in two days cure the disease. If the disease lingers, but two alternatives exist: 1. The quinin is not absorbed, due to faulty administration, in the form of pills, etc., or 2. The disease is not malaria When we hear that a Chicago malaria resists quinin, we know that another disease causes symptoms which simulate malaria, providing of course the administration technique is irreproachable. Not to encroach upon the treatment of malaria, we assert that at least our northern malaria reacts at once to quinin therapy and that, conversely, failure in treatment positively disproves a diagnosis of malaria.

103 State Street.

MANAGEMENT AND TREATMENT OF CROUPOUS PNEUMONIA.

Read in the Section on Practice of Medicine, at the Forty-eighth Annual Meeting of the American Medical Association, at Philadelphia, Pa., June 1-4, 1897.

BY D. S. CAMPBELL, M.D.
PROFESSOR OF CLINICAL MEDICINE DETROIT COLLEGE OF MEDICINE AND ATTENDING PHYSICIAN HARPER HOSPITAL, DETROIT, MICH.

In croupous pneumonia we have, I believe, a special and independent affection. Its frequent occurrence, especially during our winter and spring months, affords abundant opportunity for observing it in all its phases. And though these seasons have an undoubted influence upon its prevalence, yet from the tables of mortality we find it also occurs in the milder seasons and in every degree of latitude, wherever rapid changes of temperature with stormy winds take place, particularly with moisture. But in a climate similar to ours this is usually the exception. For it rarely makes its appearance before the colder seasons approach. But while we are conscious of the undoubted fact that these cold, moist seasons have a great bearing toward developing and spreading this affection, there are other important influences at work, which play a part in the inherent qualities of increasing its development, and these are chiefly intemperance of every kind, and poverty, especially if the individuals live in large and crowded cities, in dwellings having poor ventilation; also occupations involving exposure or over exertion, or indeed any other potent factor which might depress the vital forces of the system. as from fevers, etc. These are agencies which might be made subordinate to our surrounding conditions. Be that as it may, we find pneumonia attacking the rich and the poor alike, under every condition, favorable or otherwise, and both alike suffer indiscriminately from its toxic effect.

Now as to the nature and pathology of croupous pneumonia, it is pretty well understood to be more than a local affection or simple inflammation of the lungs. One's system may be greatly borne down by its ravages, accompanied with high fever, rapid pulse with nervous depression several days before any of the general physical signs of congestion and consolidation are manifest. In fact some may pass through an actual attack before the lesion is recognized; then danger is usually past. Besides. the smallness of the area of the lung involved, very frequently does not correspond to the ratio of the fever and the general depressing constitutional symptoms which attend it. Again, after the complaint has assumed or rather has become a local inflammatory affection, where we may have excessive cell formation, with fatty degeneration and liquefaction of the inflammatory products, with all the general physical signs and indications of purulent infiltration attending it, the constitutional effect of the disease, which usually consists of high fever, rapid or depressed pulse, great physical prostration and delirium, with other nervous symptoms, is very frequently, if not entirely, absent.

Realizing then that we have more than a local affection to contend against, a disease which I consider truly specific, infectious and constitutional in character, and which is usually of comparative short duration, and is generally ushered in with a severe chill, or followed very soon afterward with high fever, and, if complicated with either heart or renal trouble, with delirium and a general train of nervous symptoms, it clearly follows that the treatment should be directed, in the main, toward hastening the natural progress of the affection to a speedy close, so as to limit as far as possible its toxic effect on the great nerve centers, on which the strength and volubility of the heart depends to maintain life, using measures which have no depressing effect whatsoever, either on the nervous system directly or on the heart itself, thus assisting in controlling the excessive temperature, which really registers from the beginning to the close the actual termination of this fatal malady. This, in my mind. and I believe in the minds of many others of experience and observation, forms the basis of the present rational treatment of croupous pneumonia, whether complicated or not.

From this process of reasoning we are justified in assuming that there are two distinct pathologic conditions to be considered in the treatment of croupous pneumonia: 1, local disturbance, involving more or less lung tissue, with perhaps considerable structural changes, without much fever or general physical depression; 2, when the system is laboring under great nervous and perhaps physical depression, with high fever, without much local disturbance.

Now as regards the first pathologic condition, it may be laid down as a clinical fact, and this based on nearly 80 per cent. of cases, that the moment the morbific cause runs its natural course or subsides entirely, the laws governing the vital forces become active in repairing and restoring the diseased parts to their normal condition without any material assistance. But of course it is always necessary to carefully watch the local-morbid lesion, to note whether the exudation thrown out by the inflammatory act is remaining unabsorbed or the inflammation itself is becoming chronic or abscesses are forming or gangrene taking place. These and other complications are very exceptional. Interference then in such cases is not indicated or warranted, unless it be careful nursing, because the tendency is toward their own cure. For if we construe aright the morbid phenomena attending them, we will find they consist chiefly of a certain modified temperature and disturbance of the functions of the lungs by an inflammatory act, in which the former, owing naturally to its short duration and moderate amount of fever, is not sufficient of itself to cause alarm. And when it subsides the latter or local morbid process becomes completely insignificant, if not complicated.

The cases then which really demand the greatest attention, and in which material assistance becomes invaluable, are the remaining 20 per cent., the ones which are attacked very severely in the outset with prolonged rigors, and accompanied very soon with excessive fever and rapid pulse, in fact cases in which even from the beginning of the rigor great constitutional disturbance with a tendency to heart insufficiency, especially of the right side, are really anticipated.

Now then what should be the most rational form of treatment from the outset to the decline of this specific constitutional disease, judging it from its infectious nature? Can any constant or uniform method of treatment be adopted as being perfectly applicable in combating its specific properties, by mitigating its toxic influences on the great nerve centers and heart?

We thoroughly understand the chief danger arising from a severe malignant attack of croupous pneumonia. The excessive fever, labored respiration, coupled with nervous exhaustion; also the local inflammatory process, with its deposit of fibrous exudation interfering with the functional properties of the diseased section, rendering it almost impervious to the circulation, thereby increasing the impelling force of the right side of the heart, which is constantly endeavoring to limit as far as possible pulmonic retardation of the blood, are pathologic conditions always favorable to heart insufficiency, the danger to be avoided if possible. So in answer to the first question the expectant treatment presents itself, as it corresponds to the modern view of the pathology of this specific affection, by removing deranging influences- without using active therapeutic agents, unless the case absolutely demands it. And as to the second, no constant or uniform method can be adopted as sufficiently adequate in rendering material aid in cutting short the natural course of the disease, aborting its constitutional effects, unless it is by mechanical reduction of temperature, from which the expectant plan also claims some credit. But I am fully persuaded after careful observation—though this latter expedient has been extolled by eminent authorities—that such can not be accomplished. For the disease intends to and will run its natural course, no matter what one may do to arrest it, similarly to any other specific constitutional affection, as typhoid for instance. We can, however, control or reduce excessive heat by cold applications, and ease up, as often as it is applied, the one organ above all others that the system is most dependent on at this time, viz., the heart; but that only sustains and holds in reserve as it were vital energy which would otherwise be lost, should the struggle be continued unabated.

The treatment then in the management of croupous pneumonia, is best carried out in the large majority of cases, by the expectant plan already alluded to. And though the term expectant is somewhat misleading, in medical language it suggests the various means at our command, other than that of actual depletion or agents that consume the vital forces, viz., free blood-letting and the use of the general depressing drugs, as that of tartar emetic, veratrum viride, heavy doses of aconite, belladonna, etc. Hence, by adopting this system of treatment, apart greatly from the antiphlogistic plan, in the treatment of croupous pneumonia, it enlarges our views immensely, therapeutically and mechanically, allowing us to take advantage of every available means which our judgment suggests to alleviate and modify the course of the disease.

Since the heart is the chief organ upon which the burden of labor is thrown in pneumonia, it is necessary, owing to its increased functional duties, to sustain it from exhaustion, by every means possible. Now how is this best accomplished? First, let us look into the prime factor or cause of this increased exertion on the heart before the deposit of exudate in the lung exerts pressure on the blood vessels within the diseased area. From the very commencement of this affection the fever is a most constant symptom of the elevation of temperature, and it is not only constant, direct and persistent, but also appears to have a complete mastery over every physical exertion it makes. So to this excessive elevation of temperature it becomes entirely subordinate or dependent. This can be shown from the mere fact, that after the fever subsides partially or wholly, when the heart is already exhausted, feeble, but willing to pump, though the local disturbance in the lungs remain about the same, it gradually assumes its old wonted form, and excites within itself a healthy tone toward a normal action. Again, while the fever is still in the ascendency, after the exudate has been freely thrown out, and exerting pressure upon a considerable portion of the healthy lung tissue beyond the diseased section, which not only produces retardation of the blood and increases the muscular capacity of the right heart, preventing by that means the free escape of carbonic gas and other detritus which form very rapidly during fever, the very poisonous elements the system is most desirous of getting rid of, it throws additional labor on the left heart, and arrests, in a certain modified degree, the functional capacity of the respiratory muscles, and all due to the excessive fever, the chief resultant of this specific pulmonic trouble. The chief point of attack then, from the very beginning to the end of the constitutional effects of pneumonia, is the fever. But the management in the reduction requires the most careful and constant attention. To be over active and meddlesome is most injurious, and should be decidedly deprecated, while with prudence and judicious interference, it is not only possible to avert death, but even hasten recovery by sustaining the functions of the heart.

In respect to the reduction of excessive pulmonic fever, various notions and theories have been advanced regarding the best remedies at our disposal to accomplish it; but the one above all others, in my mind at least, is cold applications. And though it has long been extolled and practiced, especially by a few eminent German authors like that of Juergensen and Liebermeister, it has in great degree been held in bad repute and looked upon, in this specific disease, by the vast majority of physicians, especially in this country and England, as not only an extremely radical measure, but a foolhardy and dangerous one to follow. For my part, the experience which I have had has enabled me to save a number of lives by it, when their hearts were almost paralyzed from sheer exhaustion. Now the part which cold, judiciously applied, plays in the role of an anti-pyretic, is simply the gradual subtraction of excessive heat from the body while under the influence of pyrexia. It undoubtedly acts also, by this means, as a stimulant to the nervous system; for in all febrile conditions, destruction of the tissues takes place rapidly and they are changed into various substances of lower chemical composition. Thus through its stimulus on the great nerve centers, cold tends to eliminate these newly formed substances by the natural excretory organs, and in that way arrests its poisonous effects on the nervous system, the heart governor.

This can be clearly illustrated from the report of the following case, which recently came under my notice:

> Mr. M—, banker, aged 50, habits and general health good, was suddenly taken with several severe rigors followed soon afterward with a high fever, and though I saw him a few hours after the last chill, found him restless and delirious, with temperature of 105.5 degrees, pulse 130 and bounding. On examination I found at base of right lung slight modified dul ness, with few crepitant râles. Respiration hurried, but the characteristic irritant cough usually accompanied with tenacious rusty sputum, was still absent. He was given a full dose of calomel (15 grs.), after which cold wet compresses were applied. The action of the calomel was prompt and efficient, by disgorging the portal circulation, which necessarily relieved the blood stasis existing in the effected pulmonary tissues. Indeed, calomel, owing to its prompt action on the intestinal tract, is one of the best therapeutic agents at our command, in any of the acute infectious diseases. But I believe it is chiefly owing to its antiseptic properties in destroying the diplococci of Fraenkel, in the mouth and fauces, and the removal of the ptomains from the gastro-intestinal tract, that we owe so much to it. The result of the application of the cold wet compresses was highly satisfactory. They were applied assiduously every hour until fever was reduced 3.5 degrees. This took place after the eighth application, when they were discontinued. But whenever the temperature rose to 103 degrees they were resumed as before, and always with prompt reaction. The heart's action, after the reduction of temperature, was greatly modified, pulse fell to 100, but strong, full and regular. The delirium and restlessness, which he greatly suffered from in the onset of the disease, passed away and remained absent after the first reduction of temperature. No medicines were administered during the active stage of the disease, but when crisis ensued, which occurred on the seventh day after the initial chill, strychnia was used hypodermically (one-fortieth gr. every four hours with diluted whisky by mouth). They were discontinued after a few days for tonics and expectorants, until patient recovered. The effects of the cold wet compresses on the patient were, a clearing up of the mind, fuller and deeper inspirations, calmer countenance denoting diminished irritation of the nerve centers, sleep became more restful, and the skin and kidneys acted freer.

No doubt the constant application of the cold compresses on the surface of the body while the fever was in the ascendency, invigorated the nerve centers through the indirect stimulating influence they had upon the peripheral fibers of the skin—the latter always presenting a ruddy hue and being active in perspiration. Then the reduction of temperature lessened the amount of tissue destruction, and the vital organs, especially that of the heart and kidneys, received a rehabilitating influence from the toned-up nerve centers, which in turn resisted the toxic elements coursing through the circulation.

In the other malignant cases of croupous pneumonia, which happened to come under my immediate notice during the last three years (thirty-eight in all), and treated similarly to the one already mentioned, the temperature vacillated between 103.5 degrees and 106 degrees. In each case the organ of circulation labored hard and showed signs of exhaustion; but under this local anti-pyretic stimulant, behaved well. The cold wet packing in a sheet, and sponging the surface of the body with cold water, were the modes of application employed. This was practiced, on an average of every three hours, until the constitutional effects of the disease showed signs of waning. It usually reduced the temperature from 1.5 to 3.5 degrees, without producing the slightest discomfort—in fact the patients appeared to enjoy it. The usual temperature of the compresses was 60 degrees F.; and though pneumonia patients are as a rule very susceptible to the influence of cold application, the reduction of temperature being frequently marked after the third or fourth application, in some cases its action is not so prompt, requiring diligent and persistent effort in applying cold compresses, perhaps for hours before reduction of fever is noticed. But whenever the cooling process begins, the fever gradually continues to fall and appears to be under easier control, thereafter, than in the susceptible ones. The reason of this, no doubt, is owing chiefly to the more direct poisonous effect of the toxic elements on the sympathetic system or to its chief cervical ganglion; or perhaps to this heat-producing center being more impressionable or under more direct influence of the nervous system. But in either case, whenever the activity of the toxic agents are under control, their elimination is only a question of time when the danger mark is passed. I may be allowed to reiterate that I did not resort to the use of any direct or indirect anti-pyretic medicine internally, save the use of stimulants when cases demanded them. But while cough was severe and annoying, and pleuritic pains present interfering with respiration, I used morphia, hypodermically, in moderate doses from one-twelfth to one-fourth gr., every four to eight hours, until relief was obtained, when they were suspended. I also employed strychnia in the same manner, from one one-hundredth to one-thirtieth gr., and occasionally nitroglycerin in one one-hundredth gr. doses, when I considered the heart and circulation needed them. I used in a few instances, with good effect, hydrate of chloral in moderate doses, diluted freely with syrup and water, when patients were greatly harassed from want of sleep and rest. This drug, though considered an intense depressant upon the nerve centers at the base of the brain when given in full doses, causing more or less weakness of the heart's action, is quite different when administered in small doses. It acts more as a stimulant to these centers, and as a powerful and certain hypnotic to the cerebrum. I occasionally employed, when patients were suffering severely from either occipital or frontal headache, a combination of bicarb, soda, grains 2; acetanilid, 2; phenacetin, grains 3; codeia, grain one-sixth; one given every three hours until the desired effect was obtained, when they were immediately suspended. I consider the combination a useful adjunct. especially in some instances, in combating symptomatic cephalalgia, due to its sedative or quieting influence, without producing any depressing effects on the nervous system or heart. Also I invariably administered, as early as possible, a free dose of calomel, either alone or in combination with some mild cathartic, to start up the hepatic and intestinal secretions; repeated only when necessary. Indeed it is very important for several reasons that the functions of the stomach and bowels should be maintained, especially during the active stage of the disease. The lymphatic system is usually very active, during this time, in excreting from the blood all poisonous matters, and conveying them to the chief emunctory organs, viz.: the kidneys, cutaneous sweat glands, lungs, liver and the intestinal mucous membrane. But none of these excretory organs can be acted upon as readily as the latter during the pyrexial period, in excreting and eliminating the waste products of disintegrated tissues and other effete matters containing ptomains. If these secretions remained too long in the intestinal tract, they would naturally incapacitate the chief functional property of the stomach and bowels, that of proper digestion and assimilation, whose active duties we rely upon for nourishing support. I do not believe in too active catharsis, for it is too depleting, and tends to weaken the general system; only sufficient to cause two or three bowel movements daily. The sick room in each case was kept as well ventilated as possible, and at about 70 degrees. As far as possible, absolute quiet was maintained, with good attention to the regulation of the stomach and bowels, and the giving of good wholesome, plain nutritious diet in liquid form during the pyrexial period, and resorting usually about the period of crisis, to the use of alcoholic stimulants. I abstained from the use of all depressing drugs and cough mixtures, for from past experience I had found that they produced more or less gastric irritation, with intestinal disturbance. The hypodermic injections of the morphia salts appeared to better alleviate the pain and harsh cough.

Such, in a brief way, is the manner in which these cases were managed, suffering as they were from a malignant type of croupous pneumonia, and all but two made good recoveries without serious complications, a maximum saving of 94+ per cent., while under the old routine expectant régime I was exceedingly fortunate in saving 60 per cent. Indeed, by this plan of treatment I was able to reduce the excessive fever sufficiently to enable the heart to have some repose, which enabled it to withstand the severe muscular strain during the period of crisis. Yet I believe had I practiced the German or Continental method in the obstinate or erratic cases, that of placing them in baths and keeping them there from fifteen to thirty minutes, beginning first with a temperature of 90 degrees, gradually reduced to 68 degrees, there would have been more rapid and complete reduction of temperature and it would have remained absent longer than by the method employed.

I believe it impossible to reduce to any degree of satifaction the excessive fever in this disease by any other process without producing a tendency to heart insufficiency. The several derivatives of coal-tar products are all valuable, and perhaps in some instances reliable internal antipyretics, but they have a tendency to produce heart weakness when given in large doses, and as a consequence limit the eliminating process of the excretory organs. Salol and quinin are two very valuable remedial agents in abating pyrexia, but they too are not sufficiently potent to cause much reduction of temperature without exaggerating nervous symptoms and arresting the secretions. They are more adapted, along with the muriate, carbonate and iodid of ammonia, after the crisis has taken place and the disease become purely local, as stimulating alterative tonics; and as for any of the depressants I leave it for you to decide concerning their antipyretic virtues in cutting short or abating a true case of croupous pneumonia. For myself I have no faith in them whatever, because they are heart depressants, and when any drug assumes that particular therapeutic phenomenon, not only deficient elimination of the substances generated in excess by such excessive heat in both the tissues and blood occurs, but their retention or suspension in the system have a very deleterious or poisonous effect on the nerve centers and ganglia, and should the accumulation of urea, uric acid, carbonic acid and other detritus remain too long in the system paralysis of the vital organs would inevitably ensue and death result. Yet even several of our most prominent medical writers and observers, and indeed a very large proportion of general practitioners of apparent large experience, still cling to the old antiphlogistic plan of treatment, believing that not only better results can be obtained from its practice, but that by a sudden sharp reaction of the general circulatory organ, either by large doses of any of the selected depressants frequently repeated, or perhaps by blood-letting in plethoric cases, with the constant application of hot poultices, and perhaps sinapisms, they can abort or at least limit the inflammatory lesion of the lung to a very circumscribed area, from which little danger can be expected. This I believe is owing to their positive convictions, based on what I should term old pathologic fallacies, having for their ground work or argument that croupous pneumonia is purely a local manifestation and not the resulting pathologic lesion. If we look over the statistics, dwelling upon results obtained by the use of cold applications, coupled with the employment of some active alcoholic stimulant, as that of whisky or brandy, when actually needed, in comparison with the regular or uniform methods, viz.: By general internal medication in conjunction with hot applications externally, etc., whether in hospital or general practice we will be forced to admit, though we have to refer and rely upon Juergensen's reports compiled more than twenty years ago (for we ourselves have no such compilations of documentary materials to draw from of any account), that it had a greater saving of life by over 10 per cent. in its malignant form. Even as early as 1866 to 1876 the mortality decreased at the Basel clinic, and according to Liebermeister, in a given number of cases nearly 10 per cent. from the usual routine treatment practiced the ten years previous, a showing which is not only correct, but astounding, when considered how imperfect their practical knowledge must have been in carrying out the principles of treatment their minds suggested at so early a day, and in the face of public opinion or censure. Yet in the face of this it is equally amazing why the very laity in all our land should not only indulge in suggesting what the treatment in this subtle specific affection should be, especially when disease assumes a serious aspect, but persist in having us practice the old-time antiphlogistic plan, or the general routine treatment with hot applications, etc., when in their hearts they are forced to acknowledge they can not discriminate between the depressing effects of the one and the exhilerating virtues of the other. How this belief has become so thoroughly instilled in the minds of so many apparently intelligent persons is a mystery to me, unless it is from our own lack of self-independence and fear of public censure. But such is the fact, for I have experienced it to my full satisfaction in several instances.

Now in regard to the proper administration of diet. The food should be nutritious and easy of assimilation. Beef tea, beef, mutton or chicken broths, with eggs and milk are the most valuable articles and should be given at regular intervals and in definite quantities, four to six ounces every two hours, and if required, peptonized. And as to the use or employment of stimulants, their chief indications are the occurrence of delirium, a very rapid, weak or dicrotic pulse, especially when associated with adynamia or collapse with low nervous symptoms. They should also be given to patients who are old and feeble, who expectorate with difficulty on account of the excessive viscidity of the sputa. Blisters, hot fomentations, with or without anodynes and sinapisms are only useful for the relief of pain in the advanced stage of the disease. Dr. Beale claims that when the kidneys are in good repair large doses of either brandy or whisky may be given with good results; that owing to its direct action on the nerves of the stomach, it immediately stimulates the heart's action and thus promotes the capillary circulation. Also after the absorption into the blood it alters the consistence and chemic properties of fluids and solids and cuts short the life of rapidly-growing bioplasm, or causes it to live more slowly, and owing to its contractile influence it renders the walls of the vessels less permeable to fluids and checks the disintegrations of blood corpuscles. His opinions are well founded, but the employment of alcoholic stimulants should be used only when the case actually demands it, and that is usually about the period of crisis.

There are other symptoms pertaining to this affection which need considerable attention, but I am unable to dwell upon them now. They are all referable to the digestive organs and often cause great annoyance. Thirst perhaps stands most prominent. Cooling drinks agreeable to the patient's taste should be given freely throughout the pyrexial period.

Such then, in a brief way, is the treatment I advocate in the management of a malignant case of croupous pneumonia. I rely upon cold applications in the subtraction of excessive heat and the use of only such remedies as are adjuncts in alleviating annoying symptoms above all other measures so far advanced. Also I would advocate its use in the catarrhal forms as well and the regular cold bath in obstinate cases, as already stated, as a mode of application in preference to the other methods. I am sure it is the most valuable and reliable form of treatment at our command in combatting excessive temperatures in this disease, either in the home or at the hospital. All we want is courage and self-reliance, and good competent nurses, and unless the disease assumes a terribly malignant form, will yield to its stimulating influence and run its natural course without producing much damage to the patient.

DISCUSSION.

Dr. H. A. West of Galveston, Texas—The author emphasizes unnecessarily the purely mechanical effects of pneumonia, and leaves out of view the action of the toxins; he also emphasizes the elevated temperature unnecessarily. We do not know to what extent the high temperature may be a conservative process, and while the action of the cold bath may be beneficial, its action is probably to be explained by other facts than its mere influence upon the temperature, just as in typhoid fever its effect is upon the nervous system, stimulating the circulation, respiration and skin. So we should take into consideration the necessity for counteracting the effects of the toxins of the disease. Many patients with pneumonia are in a condition like that of a man who has been bitten by a rattle snake, and the same indication exists to counteract the toxins by stimulation. I believe there are a number of cases which can not be saved without stimulation by alcohol and by strychnin. When we come across such cases the indication is to keep the patient alive, to keep the vital powers going until nature has time to produce an antitoxin. We can do that most successfully by use of alcohol and strychnin, both given with a free hand. Many other patients will get well without any treatment at all.

Dr. **Wainwright**, Kansas City, Mo.—I believe that pneumonia requires the most scientific treatment of any disease which medical men are called to see; that more lives can be saved by the study of pneumonia and the proper application of drugs than in the treatment of any other fever. The indications for treatment so far as the heart is concerned are not, in my opinion, laid down in text-book literature. The average practitioner, when called to the bedside of a patient suffering from pneumonia, is unable to tell when alcoholic stimulants, strychnin or any cardiac stimulant is indicated. Why? We are taught to watch the pulse and study the first sound of the heart. The part of the heart to study in pneumonia is the right side. We have not exactly the same pathologic conditions present here in the right side as in hypertrophy of the left ventricle without pneumonia. In pneumonia nature makes an effort to compensate, but she has not time. If the time were long enough hypertrophy would take place in the right side of the heart in pneumonia. Then the question arises whether we shall give stimulants. In some cases alcohol and strichnin are positively and decidedly indicated, yet they are in some cases responsible for the death of the patient by causing exhaustion of the heart. When we give alcoholic stimulants it is at the expense of stored-up energies of the heart, and they ought not to be given until they are decidedly indicated. I claim that the indications for the use of alcohol and stimulants in pneumonia depend upon the state of the right side of the heart, which can be determined by careful study of the pulmonic element of the second sound. The right side fails first.

One other point relating to the pathologic condition which embarrasses the right side of the heart. In addition to the hepatized lung, there is vicarious emphysema in the healthy lung. In emphysema of the lung the right side of the heart is always greatly embarrassed.

Dr. E. B. **Borland** of Pittsburg—We have in pneumonia, not only a weak or partially paralyzed heart, but also a markedly depressed condition of the vasomotor system all over the body. Tho cold-bath treatment is in vogue both as a local and as a general treatment. The local cold treatment in pneumonia seems to me too much like imitating nature's way of chilling the body, and it is not nearly as efficient as the general cold bath in stimulating the vasomotor control of the vessels of the body.

Dr. **Campbell**—I did not have time to finish reading my paper. In reply to Dr. West I did dwell on the use of strychnin and alcohol when necessary. But what I wished to express fully was the influence of the nerve centers, the sympathetic system particularly, on the course of pneumonia. The toxins are absorbed and carried to the nerve centers of the cerebrum, and there cause paralysis, which affects the nerves, including the sympathetic ganglia, which Brown Séquard has shown to be related to the heat production of the body. Cold applications stimulate not only the vasomotor system but also the sympathetic system, getting rid of the toxins and the ptomains through the sweat glands, the kidneys and the bowels.

HOT BATHS IN PNEUMONIA.

Read in the Section on Practice of Medicine, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY JOSEPH EICHBERG, M.D.
CINCINNATI, OHIO.

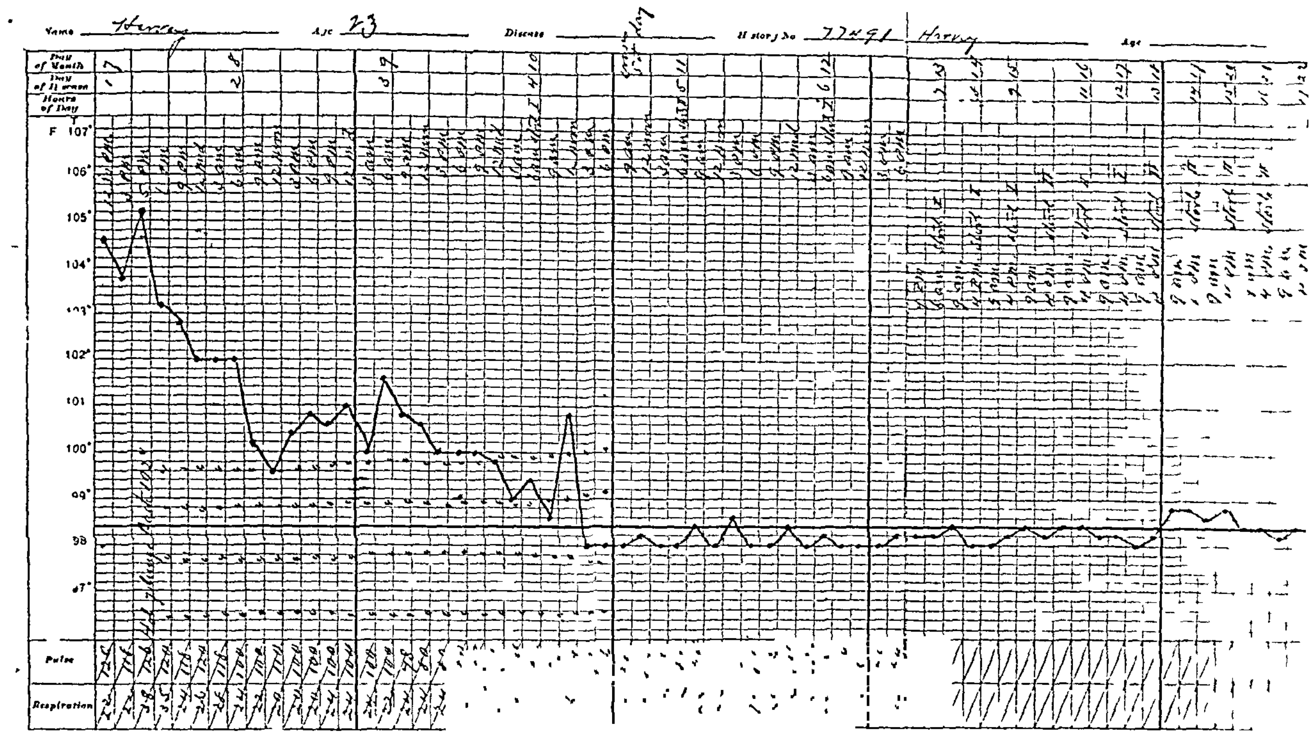
The hot bath, as employed at the Cincinnati Hospital, is given in pneumonia at a temperature of about 100 degrees. In the cases which furnish the material for this report the temperature of the water has been at times 95, at others 102 degrees; in a few cases a temperature of 110 degrees has been advised. Judged by results, no very great difference could be observed dependent upon the slight elevation of temperature in the water employed. A tablespoonful of whisky is given before immersion. The tub is moved alongside the bed of the patient and immersion of the body is complete, the level of the water rising to the chin. The stay in the bath is prolonged to ten minutes, during which time the face is frequently sponged with cold water. On emerging from the bath the patient, without previous drying of the skin, is wrapped in a warm dry blanket, in which he remains for half an hour. The bed clothing is then changed, the skin rubbed vigorously until dry and the patient left for the next three hours, when the process is repeated.

When first entering upon this plan of treatment, I thought of it only as an antipyretic measure, and the bath was advised when the body heat rose to 103 or 103.5 degrees. It was soon observed, however, that the good effects of the bath were to be found not so much in its antipyretic action, as in its influence upon the general comfort and well-being of the patient. From that time on, the bath was ordered wholly irrespective of the high or low degree of fever, and was given regularly every three hours.

I shall have occasion presently to refer to some figures. It is but fair to repeat what experience in hospital life has taught many clinicians, that in no acute infectious process are figures so likely to prove deceptive as in the case of this disease. Hospital cases of pneumonia afford, in the first place, the very worst material upon which to base working conclusions as to the value of remedial measures. Weakened by intemperance, exposure, privation or previous disease, the pneumonic process overtakes these patients at the lowest ebb of resisting power and speedily terminates a checkered existence.

Aside from this potent factor, which influences so greatly the percentage of hospital mortality, there is something in the type of the disease which makes its percentage of fatalities very variable. There are times when the number of cases received in public institutions is considerable enough to warrant the title of its epidemic prevalence; yet the number of recoveries is so great that too much is allowed for the operation of some particular therapeutic measure. In another series of cases the same plan of treatment signally fails. The startling figures of Petrescu with the digitalis treatment, showing a mortality of only 2 per cent. in upward of seven hundred cases, can be explained only in this way, since later experience has unfortunately failed to confirm the vaunted universal efficiency of this drug.

Taking all these factors into account, I am strongly inclined to the belief that we have in the hot bath a powerful adjuvant in the management of this disease; nor would I ascribe to it any secondary rank, believing it to be of almost greater importance



than any single feature of the treatment. The most powerful argument is found in the request of many patients for its repetition Strongly averse to its early employment, they soon experience so much comfort from its frequent application that in many instances patients have asked to be put in the bath before the time for its repetition had arrived.

This sense of greater comfort especially affects dyspnea, and thus strengthens tha impression now gaining ground that dyspnea in pneumonia is not dependent on the extent of pneumonic consolidation nor in any sense proportioned to it, any more than is pulse rate or temperature. It seems difficult to combat this old and at one time widely promulgated doctrine. On the day following the crisis, when the clinical picture has undergone so great a transformation, the physical signs remain unchanged. The dyspnea of the preceding period has wholly disappeared, yet there is quite as much consolidated lung as there was the previous day; and a considerable period may yet intervene before the affected lobe is wholly rid of inflammatory products. The dyspnea is to be interpreted as part of the intoxication due to specific infection, and resulting from the action of the poison on the mechanism of respiration.

It is just in this connection that the association of the skin with the mechanism of respiration deserves especial mention. Ordinarily, cutaneous respiration in the human being is of little consequence as far as the actual exchange of gases is concerned. Scharling and Hannover estimated that the exhalation of carbonic acid gas from the skin bore to the total amount the proportion of 1 to 130; Gerlach gives it as 1 to 200 So small a fraction as this could hardly influence the general well being. Much more important are the well-known experiments of Soskolow, Lang, Berne, Loschkowitz and others in suppressing the function of the skin by covering it, in its entirety or in limited portions, with a coating of some impervious material. As is well known, death promptly ensued when one-fourth or more of the skin had been thus treated; and death was not, as had been first believed, due to excessive cooling, seeing that the retention of the animals in warmed ovens only delayed, but did not avert, the fatal issue.

It could not be supposed that death was due to retention of excrementitious matter or auto-intoxication, for the blood of the animal that had thus succumbed was not toxic when injected into the circulation of another of the same species. The only probable inference was that death ensued as a result of the suppression of the respiratory stimuli emanating from the skin. The need for air, like the sense of hunger and thirst, is not a localized sensation, though referred to the larynx; all parts of the body participate in sending to the center the urgent message for more oxygen when the proportion falls below the minimum for actual consumption.

The temperature in some cases seems to be influenced but slightly by the bath, as far as immediate results are concerned, there being no strikingly rapid fall, though the general febrile course is certainly controlled in some measure; for there is almost always from the first day of the bath treatment a slight lowering of the daily average, which continues from day to day; so that the critical fall entails a drop of but two or three degrees, the temperature being nearly normal at the time of the crisis. At other times a striking improvement in the range of fever manifests itself: the accompanying chart may be fairly taken as a type of many that present an almost identical picture.

As an antipyretic, the hot bath is not less effective than many of the recognized aniline antipyretics. In my collection there is the history of one patient, a colored laborer aged 20, whose temperature on the second day rose to 105 degrees. He received 10 grains of phenacetin; one hour later another dose of 10 grains; the following hour a similar dose, the temperature still remaining at 105 degrees. When the infection is intense, no antipyretic measure is likely to be attended with very striking results. With the aid of the hot bath, many cases present a prompt decline. A laborer, aged 40, had an evening temperature of 104.6 degrees. The hot bath was given at 6, 9 and 12

.M. The temperature steadily declined until noon following day, when it was normal. It rose slowly 101 degrees on the third day, but never exceeded The crisis occurred on the fifth day. In another t after the sixth bath the fever declined from 04.2 to 99 degrees. Instances similar to these could multiplied.

The effect on the respiration, while not so striking, none the less certain. At times the change after bath is so considerable that the diminished frequency must be regarded as conservative, enabling e patient to husband his strength. In the patient ose chart is shown the frequency of respiration re the bath was 35 per minute; after the second it dropped to 24 per minute. In other cases the erence was less, amounting to 4 to 6 per minute; ven this improvement is not to be disregarded in a sease in which the resisting power of the individual s the balance for or against recovery. In another t one bath reduced the frequency of breathing 42 to 30 per minute. Two recoveries are note- rthy; one where the respirations were 80 per minute, other where for three days the rate was 60 per ie.

The greatest relief is experienced in the prompt pression of certain nervous symptoms of rather uent if not constant occurrence. Of these one of most distressing is a sense of "indefinable unrest," term employed by a colleague now passing through is convalescence from a pneumonia of the left lower be, and who, after his second bath, marveled at the idity and comfort experienced. Similarly, great efit is experienced in combating the insomnia hich enters very regularly into the early history of e attack. Delirium subsided promptly in all cases cept those complicated with alcoholism or menin- is.

It may have been mere coincidence, or it may have due to the bath, that many of our patients ed to void larger quantities of urine than did ose in the ward where this treatment was not regu- y employed. I am unwilling to express final judg- t until our observations shall have been more ly verified. It is not unlikely, however, that the il ation of the peripheral vessels following the bath y involve other small arteries in the systemic cir- ulation and thus allow of more ready filtration through e kidney.

The pulse is modified by the systematic use of the ot bath rather in its quality, than notably in fre- uency. The hard, bounding, vibratile pulse of what fathers called sthenic pneumonia, gives place to a ulse that is softer, more gradual, compressible, not in force, while wholly without the thrill con- ected with the earlier periods. In this respect the ot bath can be confidently counted upon to modify e pulse in the same manner observed after the for- regulation process of blood-letting. Indeed, the ot bath gives us the power of letting blood without sing it; by opening up the superficial arteries and pillaries, we obtain an action that equalizes the cir- on in furnishing channels other than the con- cted pulmonary vessels, to which the afflux would erwise take place. It may be that it is of no especial vantage to the patient to retain a blood undoubtedly rged with many toxic principles; but it is easier save it than to reproduce it and, as already stated, e power of resistance counts for much during a ocess essentially short and self-limited.

In how far the local process itself is influenced it might seem venturesome to say. On several occasions, four that I now recall, the first examination had shown impending involvement of an entire lung; dulness on percussion, increased resistance and diminished or absent breath sounds being found over an entire side. After the use of the bath the limitation of the process to a single lobe has been clearly evident, the unaffected lobe clearing up very promptly. This may have been occasioned by the relief of a collateral congestion which would never have advanced to consolidation, or the bath may have actually limited the distribution of the disease by prompt diversion of blood to the surface.

Still more difficult is the determination of any increased elimination of toxic material through the skin, in consequence of the bath treatment. That such toxic products exist may be inferred from the leucocytosis accompanying the disease, from the increased toxicity of the urine at the time of the crisis, as shown by Roger and Gramme; from the frequency with which death occurs by the heart at a time when convalescence seems established and acute symptoms have subsided, and from the actual discovery of the pneumococcus in the blood. Thus Kohn examined the blood in thirty-two cases with negative results in twenty-eight; eighteen of them recovered. Of the remaining nine, seven showed the pnuemococcus and died, the other two died from staphylococcus empyema. Admitting that such toxic principles probably exist, the patient's chances are only likely to be improved by stimulating the skin to further activity; the hot bath offers opportunity for doing this in the simplest manner.

Patients receiving the bath are allowed full, nourishing, concentrated diet. The bowels are moved regularly by enema. Medication has generally consisted of small doses of digitalis and strychnia. Expectorants were ordinarily not found to be necessary.

The hot bath may be given at any age. The oldest patient who recovered was 73 years old. It is universally indorsed for children, on the plea that the use of warm water prevents the nervous shock attendant on the employment of colder baths, such as are recommended for adults; but the adult patient with pneumonia also dreads his cold bath; and the necessary stimulation for the reflex respiratory act can be elicited equally well by bathing the face and head with cold water while the patient is immersed. The frequent repetition of the bath does away with the necessity for local dressings, while the interval of three hours has proven sufficient to allow for rest and sleep.

The number of baths to be administered will vary with the character and duration of the case. I can only repeat that the fever furnishes no indication for the use or repetition of the bath. The average may be given as five or six per day during the febrile period and one or two daily for several days thereafter. The largest number in my table, based upon carefully kept records of ninety cases, was given in the case of a butcher, aged 34, who had successive involvement of three lobes; each new attack supervened as the old approached the crisis, so that the acute period of his disease extended over twenty days. During this time he received 137 baths. The patient recovered. Another patient, a cigar-maker, aged 19, suffering from an old mitral regurgitation upon which the pneumonia supervened, received seventy-four baths in eleven days and recovered. A third patient, a fireman, suffering from an old caseous phthisis of both apices in addition to his pneumonia, received thirty-three baths in six days and completely recovered from his pneumonia.

Recourse to the bath from the earliest period of the disease is to be strongly commended. Naturally the diagnosis must often be deferred for three or four days, owing to obscurity in physical signs. When, however, the nature of the disease is no longer doubtful, the bath treatment should be promptly instituted. Experience has shown that the patient is thus kept in better condition and the course of the process influenced more decidedly than if the bath is given at a later stage.

Of the ninety cases forming the basis of this report seventy-one recovered and nineteen died. Four of these were moribund on admission, and of the others there was the usual contingent of chronic nephritis, pericarditis and tubercular diseases; six died quite suddenly, two on the fourth and two on the seventh day, while the remaining two succumbed when all danger seemed past, one expiring during a meal, the other just after he had answered that he was much better.

I believe that wider experience with the hot bath will but add to the conviction of its general utility in the management of one of the most fatal of acute diseases. In private practice the mortality is not so appalling, but in hospital life no other acute process claims so many victims. Where the bath can not aid in cure, it rarely fails to assuage, and it is not the least of the physician's duties to bring comfort to the sick.

DISCUSSION.

Dr. Wisner of Baltimore—I would ask the author whether there was free diuresis after the bath, and what was the temperature. I have had a considerable experience with the tepid bath in the pneumonia of children among poor people, especially among people not given to cleanliness. Repeated tepid baths, three or four a day, were sufficient in many instances without any other medication to alleviate the symptoms and hasten the cure in the cases where there was no constitutional taint to make the disease a mixed one.

Dr. F. S. Neveling of Clearfield, Pa.—I rise to favor the warm bath. With regard to the lancet, while years ago it was used too freely, I think that of late years some do not use it enough. In some cases of pneumonia especially it will give the greatest relief. I have employed it, in certain cases, more than twenty years and have never regretted it, except in one instance. I do not bleed in every case, but when I find a very severe one in the early stage the withdrawal of some blood gives almost immediate relief. I have treated no fewer than two hundred cases of pneumonia and of that number have bled, I presume, 25 per cent. It is contrary to the treatment laid down in the books and I always hesitate to say anything about it, but I have been so successful with it and it gives so great relief that I think it should be resorted to not only in pneumonia but in some other diseases as well.

In reply to an interrogatory when he used bleeding, Dr. Neveling said: When the temperature is high, the patient very restless, the lungs engorged, the heart's action embarrassed. Bleeding seems to stimulate the heart, the patient soon falls into a peaceful slumber and then perspiration breaks out. I order warm baths every three hours after that. Later judicious stimulation may be of benefit. I know that if the patient should die I would be told that I had killed him, but I have never yet lost one that I have bled.

Dr. S. Solis Cohen—What has been the influence of the baths on the urine? What about the temperature of the bath?

Dr. Eichberg—Very frequently, when the patient is taken out of the bath the amount of the urine is increased. He is wrapped in a hot blanket and left an hour without any drying, and is then dried only in case the skin is very active. As to bleeding, I felt sure that would arise in the discussion. One of the objects of the paper was to call attention to the fact that the bath took the place of the bleeding. The temperature of the bath is higher for debilitated patients. With regard to the cold water treatment, there was a man who, on sending his boy out into the world, gave him this piece of advice: "My son, honesty is the best policy. I know, for I have tried both."

CURABILITY OF PULMONARY TUBERCULOSIS.

Read in the Section on Practice of Medicine, at the Forty-eighth Annual Meeting of the American Medical Association held at Philadelphia, Pa., June 1-4, 1897.

BY E. B. BORLAND, M.D.

Clinical Lecturer, Diseases of the Chest, Medical Department of the Western University of Pennsylvania; Assistant Physician to the West Pennsylvania Hospital.

PITTSBURG, PA.

Evidence has been recently accumulating, which goes to show that tuberculosis is not only a universal but *the* universal disease. Postmortem examinations made in recent years, point to the probability that 25 per cent. is much too low an estimate of the total number of infections.

Schlenker made one hundred consecutive postmortem examinations on children and adults for this special purpose. He examined every part of the body, especially the cervical and mesenteric glands and apices of the lungs, and found 65 per cent. tuberculous. Caseous and calcareous degenerations were considered tuberculous but simple fibroid adhesions were not so considered. In over 4,000 successive postmortem examinations made in Breslau in 1893, one-third of the bodies contained gross tuberculous lesions. If the microscope had been used, probably enough lesions could have been discovered to make 2,500 infections.

Turning to pulmonary tuberculosis, Babes found lesions of the bronchial gland in more than one-half of his postmortems on children. Biggs could demonstrate characteristic lesions in the lungs alone, in 60 per cent. of his postmortem examinations. Grawitz found primary tuberculous deposits in the lungs in 152 out of 221 cases, being nearly 70 per cent. of all infections. Loomis found the bronchial glands infective to rabbits in eight out of thirty bodies apparently free from tuberculosis during life. Long before Koch discovered the tubercle bacillus, Louis laid down the rule, that if tuberculosis was found in any other part of the body it would be found in the lungs.

From the above observations, it will be a moderate estimate to say that nearly 50 per cent. of the human race are infected at some period of life with tuberculosis, and further that two-thirds of all infections are pulmonary. The greater frequency of the pulmonary over all other tuberculous infections is directly due to the inhalation of fine particles of dried sputum, containing tubercle bacilli and the pus-producing germs.

Large as the death rate (14 per cent. of deaths from all causes), when the number of cases which remain latent through life, is taken into consideration, the tubercle bacillus does not seem to be a markedly virulent germ. It requires, besides its own existence, two additional essential factors, viz., debility and abrasions, before infection is possible. Without the addition of septic germs, pulmonary tuberculosis would not in all probability, be the fatal disease it is today. The vile habit which American people have (for Europeans consider it an evidence of ill breeding) of expectorating on floors and sidewalks, has much to do with the transmission of septic germs as well as tubercle bacilli, to the lungs. All advanced cases are associated with streptococci.

While the bacillus is the keynote to the identification of tuberculosis, it has probably less to do with the fatal termination than was formerly supposed. When the blood and juices of the body contain pus-producing germs in eight out of fourteen cases, the septic germs must be held responsible for at least one-half of the destructive process.

Nature can wall up tubercle bacilli with bodies of leucocytes and connective tissue cells, for life, but can not imprison septic germs for any great length of time. If, as it seems probable, tuberculous lungs die mainly of the engrafted septicemia, then tuberculosis without sepsis or where sepsis can be avoided, is a disease capable of permanent relief. It is well known that hectic fever of the ulcerative stage, is mainly due to streptococci and staphylococci. The large proportion of cases dying of septicemia, probably explains the failures of tuberculin and tubercle antitoxins. Original investigation is always to be commended so long as there is a ray of hope, but since not a single antitoxin has been discovered, for any chronic disease, the scientific physician will do well to use, to the full extent of his ability, the older light which still shines clearly.

Tuberculosis uncomplicated with sepsis, may be considered a curable disease, in the sense that it may be held in abeyance, that is to say, kept in a latent condition for a lifetime, providing the vital resistance of the individual is kept up to the normal standard. Nature has been known to completely eradicate it in a limited number of cases. The scientific physician will endeavor to imitate nature as far as he can interpret her methods.

Investigations in search of an antitoxin have demonstrated that there is no immunity against tuberculosis when the three essential factors of infection, viz., [illegible]y, abrasions and bacilli are present. If there [illegible]s anything in the theory of immunity, a child born [illegible] infected mother ought to be less liable to infec[illegible]n after birth, other things being equal, on account [illegible] its being almost constantly inoculated with toxins during intra-uterine life.

The question arises, can tuberculosis be cured in all to all intents and purposes in its latent stage? It has been demonstrated that two-thirds of all infections either disappear or remain quiescent during an average life. If nature can accomplish so much under the reign of mainly empirical medicine, what will she be able to do when the physician concentrates all his energy on building up and maintaining the vital resistance of cell life, and keeping septic germs, as well as tubercle bacilli, away from the latent infection.

If latent pulmonary tuberculosis is to be taken proper care of and its curability further increased, it must be discovered promptly. This is too infrequently done at the present day. The early suggestive general signs of chronic indigestion, flushed cheeks, enlarged lymphatic glands, anemia, scanty or suppressed menses in the female, dislike for meats (especially fats) and the special early signs of a small localized area (in one lung) of harsh respiration which persists, usually in smaller bronchial tubes, jerking inspiration and prolonged expiration, impairment of the percussion note, especially in the apices, and a chest expansion of less than three inches, are over-looked when they ought to be discovered and their importance carefully weighed in the mind of the physician.

The curability of disease is not necessarily connected with the exhibition of drugs. In fact nature alone cures, while the scientific physician only aids her.

The hygiene of latent pulmonary tuberculosis must receive more attention if it is to be more curable. Moderately dry aseptic air containing as much ozone as possible is *the* matter of vital concern. Altitude itself has probably little influence. True, the lungs expand and unused air cells are ventilated at the expense of the life-giving element oxygen. The watchword should be, keep latent pulmonary tuberculosis as free from the death-dealing putrefactive germs as possible. Attention to the excretory organs, especially the skin, will materially aid in crushing out or keeping pulmonary tuberculosis latent. The skin throws off toxins promptly under circumstances when the other excretory organs are unequal to the task. Woolen clothing assists this excretory process; cotton checks it. Wool is a poor conductor of either heat or cold and is therefore always indicated. Nature clothes the lower animals with wool, while only foolish man insists on wearing woody fiber and as a result he suffers.

It is self-evident to any careful student of dietetics that the animal foods (except pork) require less digestive and assimilative force and elaboration, to build them up into physiologic tissue, than foods from the vegetable kingdom. Digestion may be regarded as the balance wheel and should be carefully guarded. Such agents as cod-liver oil, preparations of creosote, iron, phosphorus, strychnia or oil of cinnamon, may be employed when the vital resistance falls much below the normal standard.

Moderate pulmonary gymnastics have an important bearing on the individual's future prospects for life and health.

The author has nothing new to offer on the curability of the ulcerative stage, that is to say, the well developed mixed infection. Perhaps less than three per cent. throw off both infections and fully recover. In probably 20 per cent. the disease becomes quiescent, and remains for a number of years and is then lighted up again. The average life of the remaining 77 per cent. may be placed at two years.

Recent investigations in search of specific treatment have not discovered any factor of much value in the cure of the mixed infection. The posting and enforcing the placard "gentlemen will not, others who do not class themselves under this title, must not expectorate on floors and sidewalks," would do more to improve the prognosis of either stage of pulmonary tuberculosis than all the toxin or antitoxin treatments of the last decade, from Koch's original tuberculin down to his TA, TO and TR.

The belief that tuberculosis is inherited has done much to propagate the disease as well as to lessen its curability. Fortunately very few physicians now place much emphasis on heredity or question the contagious nature of the disease. Those who do, have not examined the almost incontrovertible proofs. Men who doubt the existence of a specific germ or question its power to do harm, are not only clogging the wheels of preventive medicine, but of curative measures as well.

Believing that pulmonary tuberculosis is a germ disease, frequently associated with the more virulent septic germs is a decided advantage in formulating a rational therapeusis. While no germicide has been discovered which will kill the germs without destroying the tissues in which they are planted, yet much can be done toward neutralizing and eliminating toxins, and even inhibiting the growth and multiplication of the germs themselves.

Too many medical men, with almost unused measures of relief within their grasp, are today lying supinely on their backs, hugging the delusive phantom of an undiscovered specific treatment, while the great white plague, with its insatiable, relentless and ruthless ally, is still destroying thousands of valuable lives which ought to be saved.

ANTITOXIC SERUM FOR TUBERCULOSIS.

Read in the Section on Practice of Medicine, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY E. A. DE SCHWEINITZ, PH.D., M.D.

DIRECTOR, BIOCHEMIC LABORATORY, BUREAU OF ANIMAL INDUSTRY, DEPARTMENT OF AGRICULTURE, WASHINGTON, D. C.

In speaking briefly of the preparation and use of antitoxic serums in my laboratory, it may be of interest to note a few points which indicated the advisability of the method I have used for treating animals to produce the desired serum.

The preliminary experiments, published in 1894[1] on the production of an immunity or resistance to tuberculosis by attenuated cultures, have been continued and are confirmatory of the first results, showing the production of great resistance and in some cases complete immunity. A detail of two sets of these experiments may be given as an instance of their general results.

TABLE 1.—Two sets of experiments showing the average of results in experiments in which the guinea pigs were vaccinated with attenuated germ and then inoculating with virulent germ.

19			14	13	14		13	13	12½	. .
20			15	18	18		20	19	19	. .

The first effect of the injection of the attenuated germ was, in some instances, to cause a slight decrease in weight; sometimes a local swelling was noted at the point of injection, and occasionally an enlargement of the inguinal glands. This disappeared after some weeks. This local swelling is probably due to the mechanical action of the bodies of the germs on account of their high fat content and possible presence of a minute amount of the acid causing necrosis. It does not always result from a subcutaneous inoculation and an apparent immunity to this action is acquired by repeated injections. This is well shown in horses and cows submitted to treatment with the attenuated germ. From six to eight weeks after the date of the injection of the germ guinea pigs seem to be entirely well, and are then inoculated with the virulent germ. As can be seen from the table, the checks died within six weeks from date of inoculation while the others, vaccinated remained well four months afterward. It has appeared, from the many experiments, that, if the inoculation with the virulent germ is made before complete recovery from the treatment with the attenuated germ the resistance is considerably less. The inoculation of the animals with the virulent germ and subsequently with a single injection of the attenuated germ showed that the latter produced a slight resistance but no very material retardation of the disease.

The production of this partial immunity or artificial resistance by means of the attenuated germ suggested already in 1894 the availability of this same material for the purpose of treating animals for the production of a serum which would have some effect in curing tuberculosis. It suggested the idea further that possibly cattle could be vaccinated with this attenuated germ and made immune to tuberculosis.

TABLE 2.—Serum from horse injected with attenuated culture used on tuberculous guinea pigs.

*Plus 1½ c.c. †Alive and well

Two cows and one heifer were selected for the work which was conducted for us by Dr. Schroeder in charge of the Experiment Station of the Bureau of Animal Industry. One of these animals was originally tuberculous, the other two healthy. The tuberculous animal received large doses of tuberculin until it had received altogether 19,407 c.c. (19⅓ liters), and as much as 1,500 c.c. of tuberculin at a single dose, from November 1894 *to April 20, 1897. The other animals* received injections of the attenuated culture, the amount injected in fifteen months being 11,425 c.c. and 18,100 c.c. respectively, and by this I mean the liquid culture media *in toto*, including the germs, just as taken from the incubator without any further treatment. At first the injection produced a slight reaction and occasionally a local edema and abscess. After they had been continued for some time this effect diminished or disappeared. The serum of all of these animals was tested a number of times. *Guinea-pigs were injected* with the serum in quantities varying from 1.5 to 6 c.c., and subsequently inoculated, together with checks, with a germ sufficiently virulent to kill the checks within four to five weeks, or the pigs were inoculated with the virulent germ and treated by subsequent injetions of the serum. Without giving the details of the experiments we may say that the serum from the cow treated with tuberculin would cause in the pigs a slight resistance to the germs, the serum of those treated with the attenuated germ produced more resistance on the part of the animals or prolonged their life to some extent but not sufficiently as compared with the quantity of material injected to make the use of cow serum appear practical. The cow serum, although sterile, frequently produced abscesses in guinea pigs. This serum we expect to test again shortly, when it should be stronger.

---

[1] Medical News, Dec. 8, 1894.

While these experiments were in progress two horses had been pressed into service. These were treated by injecting the attenuated cultures, culture fluid germ and all. The first injection of 5 c.c. caused a decided temperature reaction, local edema, stiffness, slight loss of appetite, and recovery after a few days. At first local abscesses were formed but healed fairly readily. After a time the abscess formation ceased. After eight months treatment the doses of the culture being gradually increased to 300 to 400 c.c., the total amount injected in fifteen months equaling 4,459 c.c.; the serum was used for testing. It separated out clear and well. Two sets of illustrations may be given to show its action on tuberculous animals. In one set the checks and two treated pigs died, the other two treated pigs are alive and in apparently perfect health, after a number of months. In another set the checks four in number died within four to five weeks, while the treated ones lived two or three weeks longer showing, on autopsy, much less disease in the lungs than did the checks. We endeavored, further, to isolate antitoxic substances from the serum by a slight modification of the Brieger-Boer method. We finally succeeded in obtaining a small quantity of a grayish powder, giving the biuret reaction, difficultly soluble in water, which was used for treating guinea pigs in the same way as the serum. The result was about the same as in the first instance. The pigs one-half pound in weight were inoculated with a virulent germ and treated by a single injection of 0.008 grams of this solid substance. They lived three to four weeks longer than the checks, the lungs again showing considerably less disease, while less necrosis was noted in the liver than in the checks.

The effect of the serum was also tried in preventing the rise of temperature in tuberculous guinea pigs and in saving them from a fatal dose of tuberculin. The injections of ¼ c.c. of diluted tuberculin and at the same time of ½ c.c. of the serum; either caused a decided reduction of the temperature or prevented a characteristic tuberculin reaction in animals weighing 500 grams. This is the way (at present) of gauging the effect of the serum.

The result of all this work leads me to the conclusion that the injection of the live culture produces substances antitoxic to the disease in tuberculous animals, that the quantity of this substance can be increased gradually, that the treatment of tuberculosis is and will be for some time in the experimental stage. One point, however, must be remembered, viz., that while it may be difficult to cure the disease in a guinea pig where its course is very rapid, a virulent germ requiring only from four to five weeks to kill, it might be much easier to check the disease when more prolonged in action, as in the majority of cases in man. Again, in addition to some form of specific treatment for the disease, man usually has the advantage of being placed under the best possible surroundings as to diet, climate, etc., and every effort is made to aid the improvement of the patient, while with experimental animals the conditions are different. The results obtained undoubtedly lead to the conclusion that while the treatment with antitoxic serum is still in the experimental stage and should be as yet used only in sanitariums and under the best conditions, we are on the road to success and nearer our goal than ever before. In an experimental way, the antitoxic serum as prepared in my laboratory, has been used by Dr. Stubbert at the Loomis Sanitarium, and some by Dr. Trudeau at Saranac Lake, as well as by Dr. C. W. Richardson in this city. Dr. Richardson has reported beneficial results and improvement in his patients from the use of this material. Dr. Trudeau has found that the serum causes a remarkable reduction of temperature, and Dr. Stubbert records satisfactory results. Two of Dr. Stubbert's cases will serve to indicate its general effect.

Serum from U. S. Department of Agriculture, Bureau of Animal Industry, Biochemic Laboratory, used at Loomis Sanitarium, Liberty, N. Y. Age, 14 years; American; school boy. Treatment began Feb. 23, 1897. Feb. 23, weight, 90 lbs.; general condition good; consolidation slight; no cavities; no râles; very little cough and expectoration; no tubercle bacilli; temperature normal; serum injection, 10 minims. Feb. 27, weight 91½ lbs. March 1 and 7, no tubercle bacilli: temperature normal. March 9, weight 94½ lbs; cough and expectoration less. March 15, no tubercle bacilli; temperature normal. March 25, no cough or expectoration; no tubercle bacilli; temperature normal. March 29, weight 95 lbs. Result: Gained in weight and general condition until discharged.

Serum used at Loomis Sanitarium, Liberty, N. Y. Age, 20 years, female, German, nurse. Treatment begun March 1, 1897. March 1, weight 119 lbs.; general condition good; consolidation, incipient stage, infiltration; no cavities; râles, sibilant and sonorous right lung apex to base, left lung at apex; cough bad at times, expectorates very little; temperature normal. March 13, no tubercle bacilli. March 23, no tubercle bacilli. March 29, weight 129 lbs., general condition good, no cavities: sonorous râles, second interspace, left side. April 1, no tubercle bacilli. April 7, weight 130 lbs.; râles *only on deep inspiration*, very nearly disappeared. April 13, no tubercle bacilli. Result: The patient's general condition was good when the series was started. Tubercle bacilli were present on admission in December, 1896, but had disappeared in February, 1897. There has been no unfavorable reaction from the use of serum; the rales and other physical signs have improved; she has gained in weight, coughs less and does not expectorate: she is able to take long walks and other exercise.

It may be noted that the serum used in these cases was from the same animal as the serum which cured the guinea pigs recorded above. While these results are exceedingly encouraging and there is a possibility of obtaining a serum for tuberculosis which if not specific may be very beneficial, I do not believe that investigators are warranted in recommending for general clinical use with lurid promises as to its wonderful results, a material which has not in each and every instance been tested upon experimental animals and had its efficiency actually proven.

Maragliano, Babes, Behring and Paquin are the other principal workers in the preparation of antitoxic serums. Maragliano (*Revue de la Tuberculose*, Juillet, 1896, p. 131) gives the method he has used for the production of antitoxic serum, and notes that there is present, in the cold filtered cultures of the tuberculosis germ, a substance which causes the reduction of temperature and another not destroyed by heat, which causes the rise of temperature. In all probability, without isolating the principle Maragliano was using solutions of the same substance we described in a paper before the

American Physicians, May 6, 1897. While this is not destroyed by heat, as he seems to think, it does undergo some change by probably combining with the albuminoid matter in the media and thus losing its distinct property as a temperature-reducing substance. The serum which he claims to obtain from his treatment of the animal has some effect in reducing the temperature and apparently improving the disease.

In the *Zeitschrift für Hygiene* (Bd. 23, Hft. 3), Babes, in reviewing a portion of the work on the treatment of tuberculosis with serum, comes to the conclusion that he is the first individual to have discovered any antitoxic properties in this serum, that there is an antitoxic substance present in treated animals, but that it has not yet been brought to a sufficient development to warrant general use.

Our experiments lead us to conclude, that while the injections with tuberculin produce in healthy animals, a serum containing antitoxic material the amount of this is small; and that the injection of the live culture is the proper treatment. We can not agree with the statements that horses are unsuitable for the work. Mules and donkeys may perhaps give quicker results but horses seem to be entirely satisfactory. At no time have we found that the horse serum produces toxic effects, although these have been noted from the cow serum. If the antitoxic serum treatment for tuberculosis could be freed for the present from its commercial aspect, and careful systematic experiments continuously conducted in numerous hospitals and sanitariums, this or a similar modified method of treatment could be looked to for good results. When tuberculosis can be uniformly cured in guinea pigs, as certainly as diphtheria, then does the commercial aspect become a fair and legitimate one. In the meantime the laboratory worker desires the intelligent coöperation of the clinician who will be desirous not only of curing his patient, but of advancing the theory as well as the application of those principles which, with the expenditure of many years time and often at great personal risk, have been made intelligible.

INTERRUPTED RESPIRATION; A STUDY OF CERTAIN PHYSICAL SIGNS OF DISEASES OF THE CHEST.

Read by title in the Section on Practice of Medicine, at the Forty-eighth Annual Meeting of the American Medical Association, at Philadelphia, Pa., June 1-4, 1897.

BY J. N. HALL, M.D.
PROFESSOR OF THERAPEUTICS AND CLINICAL MEDICINE, UNIVERSITY OF COLORADO.
DENVER, COLO.

The very unsatisfactory condition of our knowledge, as presented in our text-books, regarding the causation and significance of those physical signs grouped under the general head of "interrupted respiration," has led me to study these signs with considerable care for some years, and I present today some of the results of this study.

It is apparent at the outset that, by different writers, several totally different signs are considered under the general terms, "interrupted, cogwheel and wavy respiration," including irregular inspiration from weakness of the respiratory muscles; irregular action on account of painful affections, as pleurisy, pleurodynia and intercostal neuralgia; cardio-respiratory murmur; irregular inspiration from excitement, affecting either the respiratory mechanism itself or the heart, producing a systolic interruption in the latter case, covering the whole chest in certain cases; interruption from the presence of swelling of the mucous membrane of the bronchi; from the presence of gelatinous mucus in the smaller tubes; from outgrowths of tubercles into the caliber of the tubes; from compression of vessels of the lung by contracting pleurisy, or by fibroid or other contractile processes in the lung itself; from pleural adhesions, and possibly from other causes.

In order, then, to arrive at a proper conception of its real value, we must define more narrowly what we mean by interrupted respiration, for it is obvious that some of the phenomena we have spoken of have no pathologic significance. Let us investigate the different matters we have mentioned.

Flint, Powell and others speak of irregular rhythm heard over the entire chest in perfectly healthy persons of very nervous, excitable temperament, due to irregular or spasmodic action of the muscles of respiration, as in crying children or sobbing women The mere mention of this form of irregularity will suffice, since it has no importance in diagnosis or pathology.

The disturbed rhythm caused by the painful affections just mentioned should be so obvious as to its causation as to present nothing of interest in this connection, for it has no known connection with any pathologic condition of the lung tissue proper.

The interrupted respiration from weakness of the respiratory muscles, mentioned by Liebermeister, is of importance only because such weakness would probably predispose to the development of tuberculosis, since decided inactivity of the lungs must follow as a result. I have not recognized this form of respiration.

Many writers have spoken of systolic interruption, ordinarily as occurring on the left side only, especially in front, and upon inspiration, the inference, avowed or not, being that it is due to the compression of air in the lung, and consequent displacement of that in the bronchial tubes, directly by the heart's action (the so-called cardio-respiratory murmur). The fact that such a condition exists upon auscultation over the entire chest during excitement, occasionally, would lead to a consideration of the possibility of its being due to an unusually forcible current of blood passing through normal arteries in the lung tissue, possibly thus changing its volume, by unusual filling of the vessels, so as to influence the air contained in the tubes. The possibility of such a phenomenon from aneurysm or dilated aorta, must also be borne in mind.

It is much more common, I think, to find systolic interruption of respiration in cases of fibroid phthisis, especially upon the left side, in which decided contraction of the affected lung has occurred. The description of a recent case of my own, in which this phenomenon was exceedingly well marked, will answer for that of the group in general:

W. P., male, 26 years of age, of good heredity, had pleurisy with effusion six years ago, and developed a slowly progressing phthisis. At the present time he has a decided retraction of the left apex, the shoulder being one and a half inches below the right, and the heart being so much drawn upward and to the left that its apex is found in the fourth space, slightly to the left of the nipple. Much of its anterior aspect has been uncovered by the retraction of the lung, giving rise to increase in its dulness. Over the left lung above the fourth interspace are found decided dulness, loud bronchial respiration, bronchophony and occasional coarse moist and leathery râles, the latter with a creaking character. Interrupted respiration has existed in parts of the left lung for some years.

At present, most markedly over the left back, between the left scapula and the spine, where there is a fair resonance, and somewhat below this area, may be heard, when the patient takes a slow inspiration, a systolic interruption of inspiration so marked that the heart's action may be observed with as much ease, so far as the estimation of its frequency is concerned, as over the precordial area. During expiration the interruption is less marked, but still easily heard. The sound is exactly that obtained by pressing with the bell of the stethoscope over the subclavian artery in many tuberculous patients, excepting that it is fainter and less distinct. It certainly has to me every appearance of being caused by the forcing of blood through arteries narrowed in caliber by pressure from without. In this case such narrowing might have been caused either by old thickening of the pleura, or by fibroid contraction of the lung with resulting compression of its contained arteries, or by both processes acting in conjunction. It seems probable that the branches of the pulmonic artery are the ones involved, because of their much greater size.

If this phenomenon were due to displacement of air in the bronchial tubes (as mentioned by certain authors), by the expansile pulsation of the heart, it should be much more common than it is, and in this case should be found near the heart in front, as well as in the back. Under either hypothesis, however, we may account for the fact that such interruption is often found on the border of the contracted lung, where there is but slight if any dulness, for the sound might be as easily propagated in the tubes as in the blood vessels.

Sahli and others have thought that in certain cases interruption of respiration occurs from the presence of gelatinous mucus in the smaller tubes, yielding slowly to the in-coming current of air, a theory accounting more satisfactorily than any other, I believe, for those cases in which the interruptions are not synchronous with the cardiac pulsations, and in which the sign under discussion is confined to a region bordering upon a localized area of tuberculous infiltration, particularly in the apex of the lung. To my mind, the chief objection to the explanation lies in the fact that the sign is more constant in a given case than such an origin as that mentioned would lead us to anticipate.

Some cases are thought by Sahli to be explainable upon the ground of a swelling of the mucous membrane lining the tubes, yielding in a valvular manner to the advancing air current; but probably not to the expiratory wave, we should be obliged to infer, because of the comparative rarity of the phenomenon in expiration. It seems that some of the cases, presenting what to me sound like two or three distinct suction sounds during the course of inspiration, are best explained upon this hypothesis.

Musser mentions stoppage of the current of air by outgrowths of tubercle. While certainly possible at times, such an explanation could scarcely apply in any great number of cases, since the sign is too often seen in the chests of patients in whom, from the history and the physical examination, there can be no grounds for the belief in the existence of such tubercles.

Powell once saw the most marked interruption of respiration in a case in which autopsy showed a cavity with a small aneurysm near its margin. The signs of a cavity were also present. This is obviously an exceptional case.

There seems to be reason in the suggestion made by Walshe, that possibly interrupted respiration may occur "from textural disease in the lung itself, causing a want of uniformity in elastic and expansile power." In some cases, Walshe believed that pleural adhesions might act in similar manner to prevent the regular and uniform expansion of the adjacent lung tissue.

I can not understand how subpleural nodules could cause a friction sound so resembling the sign in question as to deceive the experienced ear, although Ruehle apparently thought so. His theory of the compression of the bronchi by nodular growths, which might certainly interfere with the passing air current, seems tenable under certain circumstances, however, these acting in the same way that outgrowths of tubercular tissue or swelling of the mucous membrane may act.

I think we may reasonably conclude, then, that interrupted respiration may originate in so many different ways that but little importance should be attached to the sign excepting as a confirmatory one, especially in conjunction with more reliable ones, such as bronchial râles, dulness, bronchophony, bronchial respiration, and particularly broncho-vesicular respiration. The presence of the sign should always warn us to seek more carefully than otherwise for further signs of respiratory disease; while in certain cases, in which one could possibly decide with reasonable certainty that the interruption was due to some particular one of the several causes mentioned, he would be justified in basing his judgment of the case to a certain extent upon this factor.

IMPROVED METHOD OF COCAIN ANESTHESIA.

BY J. F. OAKS, M.D., PH.C.

CHICAGO.

My apology for the following polemic on a brief article entitled an "Improved Method of Cocain Anesthesia for the Nasal Mucous Membrane," which appeared in the JOURNAL of May 22, p. 976, is the fact that the general use of so dangerous a drug as cocain demands our scrutiny of the various methods of its employment. In the article referred to Dr. Anderson gives his method of local anesthesia, which consists in a preliminary use of a one-tenth per cent solution of cocain as a spray to the nasal mucosa, which after being repeated in thirty seconds is followed by the use of a 25 per cent. solution on a probe, armed with a whisp of cotton.

The object of this kindly criticism of Dr. A.'s method is to check any tendency the article might create to the too bold and free use of that dangerous drug.

The "preliminary spray of a one-tenth per cent. solution" may appear to some to be unnecessary, yet it is believed by some authorities that the preliminary generalized use of cocain in the nasal cavities insures a better and more satisfactory anesthesia, where it is followed by the local application of a stronger solution, and that this result can be obtained with a less amount of the drug. It should not be forgotten, however, that a special spray apparatus or tip should be used for cocain- solutions. The Davidson sprays so commonly used throw too coarse a spray, and in the absence of any control of the compressed air supply the spray is distributed too freely and that beyond the nasal cavities into the post-nasal space, which is not only unnecessary and undesirable, but quite discomforting to the patient. After the "preliminary spray" Dr. A. uses a 25 per cent. solution "by rubbing the probe, on which is arranged a small amount of cotton, back and forth gently, but continuously, allowing the cocainized cotton to reach every desired part of the membrane," intimating in the same paragraph that "anesthesia will take place in from three to five minutes."

Many of us who have had some experience of a not very pleasant kind, even from the use of solutions much weaker than a 25 per cent. solution, would not be so likely to follow Dr. A.'s "method," but "there are others" who would be specialists, that might realize the danger too late, especially in the case of an individual with a peculiar idiosyncracy. Therefore I must warn such against so free a use of so strong a solution of cocain in the nasal cavities.

In summing up the advantages of his method Dr. A. claims a saving of time, "not requiring more than three to five minutes, while the tampon method is fifteen to thirty minutes." The latter statement is contrary to the experience of most nose and throat specialists. Although time and space will not permit me to either defend or condemn the so-called "tampon method," suffice it to say that when correctly used (*i.e.*, by placing in contact with the mucosa a thin layer of cotton fibers moistened with a 5 per cent. solution of cocain covering a little more than the operative area, thereby limiting absorption and controlling toxic effects) is all sufficient for cautery and the various intra-nasal operative procedures. Dr. A. asserts that by his method a small amount of cocain is used, yet it is to be supposed that the rubbing of the probe charged with cocainized cotton back and forth continuously for from three to five minutes would permit the absorption of a sufficient quantity of the drug to produce decided toxic effect in persons only moderately susceptible to it.

He also asserts that the equal distribution is more desirable than the localized effect, for cautery, etc., which is true only in part, as explained in the first part of this communication. He furthermore asserts that "the admixture with mucus does not dilute nor lessen the anesthetic effect." Granting this latter statement to be true, the argument would be in favor of the method he incorrectly calls the "tampon method."

The suggestion of Dr. A. "to arrange the patient in the prone position, as for general anesthesia," is entirely gratuitous, since it is neither necessary nor convenient, in view of the difficulty to obtain hemostasis in operative procedures within the nasal cavities. It is a fact that the free hemorrhage so usual in intra-nasal operations makes the upright position imperative.

In conclusion, I would reiterate the statement that a 5 per cent. solution of cocain will be found all sufficient to secure the desired anesthesia of the nasal mucosa. In endolaryngeal operations, however, and in the post-nasal vault the careful use of a 10 per cent. solution is more satisfactory. I consider a 25 per cent. solution either in the nose or larynx to be recommended in exceptional cases only.

126 State Street.

A CASE OF BENIGN CICATRICIAL STRICTURE OF THE ILEUM.

OPERATION, LATERAL ANASTOMOSIS. EXHIBITION OF SPECIMEN REMOVED FIVE YEARS AFTER.

Read at the meeting of the Chicago Pathological Society, April 12, 1897

BY M. L. HARRIS, M.D.

Professor of Surgery, Chicago Policlinic.

The patient from whom this specimen was obtained presented the following history: Mr. C., age 57, American, married. Family history good. His health previous to the present trouble had been good. I could obtain no history of a former intestinal trouble such as dysentery, severe diarrhea, typhoid fever or any illness likely to have been attended by the formation of an ulcer or ulcers in the intestinal tract. He could date his present trouble back about three years. It began very gradually with symptoms of indigestion or dyspepsia, and for a long time was supposed to be due to his drinking habit, as he was a man who indulged rather freely in intoxicants. The symptoms, however, continued to increase in severity, unrelieved by medication. The bowels became constipated, with periodic attacks of diarrhea. His appetite failed and he wasted greatly in strength and flesh.

When seen by me Dec. 10, 1891, he was in an extremely miserable condition. He had wasted to a mere skeleton, weighing but 85 pounds. He was unable to retain nourishment, as he vomited everything put into the stomach. The ejecta were very offensive and semi-fecal in odor. Nothing had passed the bowels for several days.

An examination of the abdomen showed it to be somewhat distended. Large coils of small intestine were distinctly outlined through the abdominal wall and the peristaltic contraction was plainly visible. During these peristaltic waves, which were intermittent, the patient would experience severe griping pains. I have never seen coils of intestine so distinctly outlined and the peristaltic wave so plainly visible as in this case. Upon palpation an indistinct sense of resistance could be felt deep in the lower part of the abdomen, a little to the right of the mid-line. With the finger in the rectum this was more distinct, yet a tumor could nowhere be defined. The urine was normal except for the presence of a large amount of indican.

A diagnosis of chronic intestinal obstruction was easily made. Its location in the lower portion of the small intestine seemed likewise quite clear. Whether malignant or benign, however, was not so easily determined. His age and great emaciation spoke for malignancy. The length of time, fully three years, during which distinct symptoms had been present, the rarity of carcinoma in the small intestine and the absence of a tumor in an emaciated abdomen easily palpable, spoke more in favor of a benign stricture.

With this in view I determined to operate at once and form an anastomosis around the obstruction. The operation was performed Dec. 11, 1891. Upon opening the abdomen, the seat of obstruction was fortunately quickly reached and the loop drawn out. A linear mass of cicatricial tissue about 1.5 cm. in width, apparently involving most of the thickness of the gut wall, encircled the intestine, and by its contraction had almost completely obliterated the lumen of the canal. It did *not* extend at all on to the mesentery, which was perfectly free. It was evidently a simple, benign cicatricial stricture, and was located in the lower part of the ileum. The intestine below the stricture was very small, flat and empty, while above it was remarkably dilated, looking like a distended colon, its wall, from hypertrophy, being as thick as that of the stomach. A lateral anastomosis was made between the loop above and the one below the stricture, about 30 cm. being excluded from the intestinal current. Senn's large size decalcified bone plates were used in the operation. The recovery from the operation was rapid and without incident. He regained his health at once and made the most remarkable gain in weight, from 85 to 190 pounds in eleven months.

He continued in good health for about four years, when the effects of chronic renal and cardiac disease, aggravated or perhaps superinduced by his habits, began to show themselves, and from this time on the usual course of these diseases was passed through—general anasarca, ascites with repeated tappings, etc., and finally death in December, 1896, exactly five years after the operation. At no time was there any trouble with his intestinal tract after the operation. The specimen still shows the thick cicatricial mass forming the stricture and allowing but a small probe to pass.

The loop of intestine which was excluded has shrunken or atrophied to but a few cm. in length. The anastomotic opening is of good size, having contracted but little, and permits a free unobstructed passage of the intestinal contents. The great dilatation of the bowel above the stricture has all disappeared, the gut being now of uniform size. This is, so far as I am aware, the oldest specimen—five years—of a lateral anastomosis on record.

The cause of the stricture was in all probability cicatricial contraction following an intestinal ulcer, but the history of the patient gave no clue to the primary trouble, and no examination of the body or intestines was permitted after death.

A CASE OF DEFECT IN THE VENTRICULAR SEPTUM AND STENOSIS OF THE PULMONARY CONUS IN A MAN THIRTY-TWO YEARS OLD, WITH DEMONSTRATION OF THE HEART.

Read at the Meeting of the Chicago Pathological Society, April 12, 1897.

BY JOSEPHINE E. YOUNG, M.D.

CHICAGO, ILL.

October 2, 1896, a patient, 32 years of age, entered Cook County hospital, Chicago, with evidences of an acute, febrile disease. He gave the following history: When 2 years old a consultation of physicians was held—the child always having been so delicate that it was necessary to carry him about on a pillow, at that time being very poorly nourished and developed, unable to walk, and having at frequent intervals attacks of marked cyanosis. The consultants told his mother that he could not live to maturity. At the age of 17, Prof. Lyman of Rush Medical College demonstrated the case in his clinic as one of cardiac disease. During his entire life, upon marked exertion or excitement. the patient had attacks of pronounced cyanosis.

Upon entrance to the hospital, physical examination revealed the following: General development and nourishment good, clubbed finger ends, color ruddy, no evidence of cyanosis at this time. The pulse was full and regular, later becoming irregular and distinctly subingual. *Heart:* percussion, relative dulness *right border* to the right of the right sternal line, *base* third rib, *left border* left mammillary line. There was increased dulness when the patient leaned forward. One month later the dulness extended two cm. to the left of the left mammillary line. Palpation: upon entrance there was distinct fremitus over the entire precordia. The apex beat was strong and regular. One month later there was marked arrhythmia. Auscultation: a very loud systolic murmur could be heard over the entire thorax, anteriorly and posteriorly, the maximum intensity being at the junction of the third rib with the left border of the sternum. The murmur was heard very distinctly along the entire left sternal border. There was no accentuation of the second pulmonic tone. Notwithstanding the fact that for eighteen days the temperature remained at or near 103; there was never any cyanosis. The urine was negative, both as to albumin and morphologic elements. Other findings bear no especial relation to the cardiac lesions, the diagnosis of the acute disease halting between acute endocarditis and typhoid fever. Dr. James B. Herrick at this time made a diagnosis of congenital heart disease.

The patient was discharged Nov. 24, 1896, after recovery from the acute attack. Dec. 12, 1896, he reentered the hospital with facial erysipelas.

The heart and lung findings were as before. In a few days, with a temperature of 104 degrees, cyanosis became a marked feature. The heart was very arrhythmic, the pulse correspondingly irregular and compressible. The spleen extended five cm. below the left costal arch, the liver one and one-half cm. below the right costal arch and in the mammillary line. Examination of the urine showed albumin in rather large amount and granular casts. The extremities were not edematous. Two days before death the dyspnea was extreme and respirations increased to fifty-two. The patient's critical condition and constant right decubitus prevented a thorough examination of the right lung, which later showed evidences of pneumonia. He was rational throughout.

Death occurred Jan. 12, 1897, after one month's illness, during which time the temperature was frequently 104 and 105 degrees.

The clinical diagnosis was facial erysipelas, acute splenitis, nephritis, pneumonia (?), general septic infection, and congenital heart disease. The autopsy was mrde by Dr. Ludwig Hektoen, Jan. 18, 1897.

Anatomic diagnosis: healed facial erysipelas, lobar pneumonia, embolic abscess in the left lung, acute splenic tumor, chronic and acute nephritis, chronic gastritis, pigmented Peyer's patches, hypertrophy of the heart, chronic and acute endocarditis of the tricuspid and pulmonary valves and the wall of the right ventricle, stenosis of the pulmonary conus and congenital defect of the ventricular septum.

The bacteriologic examination of the organs showed staphylococci pyogenes albus and citreus to be present everywhere.

The cardiac findings more particularly are the following: The hypertrophy is rather marked; the heart weighs 400 grams; the apex is composed equally of the right and left ventricles; the wall of the right auricle measures 4 mm. in the thickest part, that of the left auricle 3 mm.; the wall of the right ventricle averages 1 cm. in thickness, that of the left ventricle 1½ cm.; the circumference of the aorta at the valvus is 5.7 cm., that of the pulmonary artery is 5.4 c.m.; the ductus Botalli is closed; the arrangement of the pulmonary artery is normal, that of the aorta, which communicates only with the left ventricle, is normal also. Four cm. below the upper margin of the pulmonic semi-lunar valves there is a stenosis of the pulmonary conus, due to fibrous tissue. The lumen of the conus measures 1 cm. in its largest diameter; the foramen ovale is patent, admitting a lead pencil through its orifice; a sickle-shaped valve covers it. Directly below the semi-lunar valves of the aorta there is a defect in the ventricular septum which measures 2.6 cm. in the horizontal diameter, 2 cm. in the vertical diameter. This defect corresponds to the septum membranacum, or undefended space, the last part of the ventricular septum to close, composed normally of a thin layer of fibrous tissue covered with endothelium. The pulmonary valves are thickened; the free margins of the posterior segment are covered by large polypoid vegetations. These spring also from the ventricular surfaces of the valves and from the wall of the pulmonary artery. The free margins of the tricuspid valves are thickened. Here then are distinct polypoid vegetations. The orifice admits four finger-tips easily; the right auricular appendix shows some irregular masses; the aorta valves are free from thickening; the aorta shows no atheroma; the mitral valve is normal, admitting four finger-tips snugly; the myocardium, except at the stenosis of the conus, is normal. Microscopically, the striæ and nuclei of the fibers are normal, but there is a general segmentation.

The clinical diagnosis of congenital heart disease was based upon the history, the cyanosis, hypertrophy of the right heart, position of the systolic murmur and thrill at the junction of the left third rib with the sternum, the intensity and widespread transmission of the thrill and the weak second pulmonic tone.

As to the formation of the lesions, Fraentzel, Bamberger and Oppolzer support the Hunter-Morgagni theory, a myo- or endo- carditis occurring before the eighth week of fetal life is the cause of the stenosis of the pulmonary artery or its conus. This greatly increases blood pressure by preventing the proper escape of the blood from the right ventricle, the blood necessarily forcing its way into the left ventricle through the undeveloped septum. If the opening in the septum is sufficiently large blood pressure in the right heart is compensated for—there may be no opening (in the septum) of the foramen ovale. If not large enough there will be hypertrophy and dilatation of the right ventricle, stasis in the right auricle, with passage of blood through the foramen ovale, which remains patent.

The case is of interest not so much from its rarity as from the following points: The patient had reached the age of 32, was a strong, well-developed man doing the ordinarily heavy work of a laborer, had passed through an acute febrile attack of eighteen days' duration without any evidence of cyanosis, had resisted for a month profound erysipelatous and septic infection and had entirely escaped pulmonary tuberculosis, a condition frequent in these cases, owing to the diminished supply of blood sent to the lungs.

A Progressive Potentate.—The young Emperor of China, with a lost faith in the traditional remedies of his people, has dispatched to the medical centers of Europe a large number of students. London, Paris, Berlin and Vienna have already received a respectable installment.

ADAPTATION AND INSERTION OF AN ARTIFICIAL EYE; ENUCLEATION, SYMPATHETIC PHENOMENA, ETC.

BY WILLIAM B. MEANY, M.D.
MEMBER OF THE AMERICAN MEDICAL ASSOCIATION, ETC.
SAINT LOUIS, MO.

The exercise of a little care with "troublesome" cases in the taking of a caste—either with dentist wax or with superfine dental plaster-of-paris—of the tissue walls of the orbital cavity resulting from the removal of an eyeball, and the artificial eye to be inserted fashioned on the lines of the "model," may overcome the difficulties complained of by advocates of dangerous substitute proceedings for the benign operation of enucleation.

An artificial eye should be fabricated to meet the requirements of the anatomic conformation of the orbital cavity, rather than the adaptation of the tissue walls to a misfit or bespoke eye—which has never been known to vary from its present shape for half a century or thereabouts.

By the adoption of this plan of procedure hazardous and unwarrantable "operations" that permit the retention of a portion of the structure of an eyeball that has become or is liable to take on disease at any moment, and thereby incite sympathetic phenomena, will be avoided; and the present unsatisfactory process of "grinding down" of the shop (stock) eye be dispensed with.

The insertion of an artificial eye is very simple and is soon learned by the patient. It must first be steadily pushed beneath the upper eyelid and held there while the lower lid is brought around its lower edges.

Its removal is readily facilitated by depressing the lower lid so as to expose the lower edge of the artificial eye, when it usually slips out by its own weight, and should be caught in a handkerchief or permitted to drop out upon a bed. An artificial eye should not be adapted or inserted until the cicatrix of the conjunctiva and other tissues of the orbit become firm, quiet and free from ulceration or inflammatory discharges. By selecting an artificial eye somewhat smaller than the remaining or sound eye, the distorted or over-exaggerated appearance is avoided. The eye should not be worn continuously—that is, never during bedtime.

ENUCLEATION.

This operation or excision of the eyeball is usually performed as follows: A fold of the conjunctiva on the inner or nasal side of the eye having been seized with the forceps is divided with a scissors at the corneo-scleral juncture along its entire circumference. The tendons of the muscles caught up with a strabismus hook and divided, the globe turned firmly outward and forward; the scissors (those curved on the flat being used), introduced either on the nasal or temporal side of the eye as the operator may elect. the blades of the scissor being separated so as to straddle the optic nerve, permitting of easy division. Care should be taken to excise the nerve some distance from its ocular attachment.

The globe being brought out of the orbit, the oblique nerves and vessels are divided. The cavity is then carefully syringed with a cold boric acid or a 1 to 10,000 sublimate lotion, or both: the slight hemorrhage that follows the operation is usually arrested by the "syringing" of the cold antiseptic solutions

A suture uniting the superior and inferior margins of the conjunctiva introduced; a rondelle of antiseptic cotton wool previously moistened with distilled water is inserted between the lids and a compressive bandage applied, and permitted to remain for twenty-four or thirty-six hours.

The stitches uniting the superior and inferior margins of the conjunctiva are generally removed on the second day following the enucleation.

The following operation has been suggested a decade or more ago and appears to possess the important advantages derived from the operation of enucleation with none of the disadvantages of that of evisceration, as proposed by Mr. Mules, or other "operations" that do not materially differ from evisceration other than as to the method in removing a little more or less of nerve tissue, and the dangers arising from sympathetic trouble being almost *nil* when compared to the so-called surgical interferences that permit the retension of a portion of the structures of a globe that has already become or is liable to take on disease at any moment.

The operation is similar or in fact is practically identical with that of enucleation with the addition of a sterilized hollow glass sphere (to avoid the dangers of a sphere becoming fractured one made of silver or aluminum has been suggested as a likely substitute) is inserted into the cavity of Tenon's capsule and the conjunctiva stitched firmly over it; a temporary catgut drain will have to be used in conjunction with the operation.

When the eyeball is entirely removed as in this operation there is no likelihood of disease being propagated and thereby displacing the questionable practice commended by a writer in an article of a late date, of the "ingrafting" into the tissues of the orbital cavity portions of so dangerous a substance as the "deadly" sepsis-generating sponge, to act as a "support" for an artificial eye.

Advocates of "substitutes" for enucleation who, for reasons of their own, appear unable to obtain a proper support for an artificial eye following their enucleations, will find a useful and movable support, as the muscles of the eyeball are attached upon the sphere inclosed within it; as Tenon's capsule is attached to the conjunctiva in front, when this is sutured the capsule is rendered tense and becomes accurately adapted to the selected sphere. This operation, however presents some disadvantages.

The operation of enucleation is wonderfully benign and if carefully performed does not in the least interfere with the adjustment of an artificial eye, whose motility will be as perfect as if resting upon a shrunken globe, besides being free from the dangers of a shrunken remnant of a lost eye, acting in the same prejudicial manner as an injured or diseased eye before having parted with its contents or a portion of its structures. A most happy effect is gained by enucleation, in arresting and subduing the *irritation* which threatens to develop into *destructive* inflammation of the sound eye.

Enucleation at an early stage should be insisted upon where eyes have been crushed by blows, that are the *site* of neoplastic growths that may prove malignant; eyes that have been penetrated by foreign bodies which are not removable, which belong to patients who can not be trusted to take either proper care of themselves or to return if they are threatened with sympathetic *irritation*.

When the exciting eye is evidently rendered useless by the wound or from consequent inflammation, that is when its vision amounts to perception of light, and when there is no probability that sight will improve without incurring the risks of the sympathizing eye, the exciting eye should immediately be excised. If the sympathizing eye is only suffering from *irritation* and presents no symptoms of *inflammation* the removal of the exciting eye will be followed by immediate relief of the irritation and no symptoms of inflammation are likely to appear; hence the necessity of an early enucleation of useless eyeballs from persons in whom one sound eye remains as a prophylatic measure. Advocates of such "operations" as abscission, neurotomy, optico-ciliary neurotomy, exenteration or substitutes of a like character that permit the retension of a portion of a diseased globe, can hardly advance any claim to merit, save to afford *only* temporary relief from sensitive and painful eyeballs without offering the least safeguard to the prevention of sympathetic phenomena or destructive inflammation of the sound or remaining eye.

The operation of enucleation should alone be practiced, and the "substitute" procedures adopted and advocated every now and then by some youthful or experimental surgeon, inhibited by law.

3907 West Belle Place.

A NEW SPLINT FOR NASAL FRACTURES AND DEFORMITIES.

Read at the Third Annual Meeting of the American Academy of Railway Surgeons, held at Chicago, Sept. 23, 24 and 25, 1896.

BY JESSE HAWES, M. D.,

DIVISION SURGEON ON THE UNION PACIFIC, DENVER AND GULF RAILWAY, GREELEY, COLO.

This splint is intended for cases of nasal fracture in which there is a drawing upward of the point of the nose or of the alæ. Permit me to describe it by the narration of a case in which necessity demanded it

C. W., boy aged 10 years, was brought to me, having been kicked by a horse several days before. The toe of the animal struck the nasal septum at its junction with the upper lip. The blow cut the septum loose from the lip. A wound extended through the septum from the point of union with the lip directly upward for three-fourths of an inch.

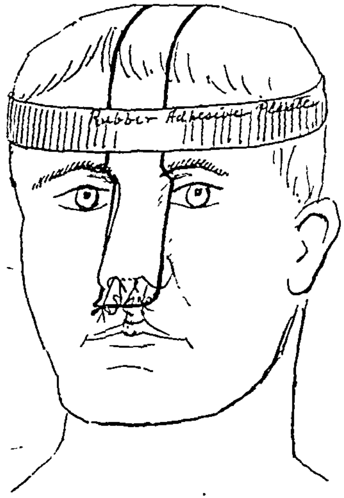
The detached edge of the septum was rolled up into the nose; both alæ were forced upward; the nasal bones were detatched from the maxillary and driven upward, and small pieces of the maxillary were broken on each side of the nose. The contractions of the levators of the nose held the soft and hard tissues where they had been driven by the kick. The point of the nose was far above its normal position; the right ala was much higher than the left.

The first step toward repair must be to bring down and fasten the septum in its position, the next to replace the fractured bones, the last to bring down and retain in position the upturned nose. To fasten the septum by stitches was simple; the nasal bones were easily pressed into their normal position, but slipped outward as soon as manual pressure was removed. To bring down and *retain* the point of the nose in its proper place was impossible.

The best suggestion I could get from "the books" and experience was to draw the nose down by grasping its point, then to transfix the lower end of the septum antero-posteriorly with a long, stout, steel needle, the point of which was driven down in the palatal process of the superior maxillary. (See illustrations in Roberts' Surgery.) While this partially held the point of the nose from being drawn upward, it did so very imperfectly; the upward dislocation of the alæ was corrected but very little. The quite recent editions of Bryant, Keene, Ashhurst, Stephen Smith, Wyeth, Roberts, Ashhurst's Cyclopedia, Hamilton's Fractures, Holmes, Gross and Stimson offered no helpful suggestion.

After several days of chagrin over my inability to control the deformity, the very simple nasal appliance which I here present suggested itself.

It consists of a piece of No. 15 spring brass wire of suitable length, bent first into the form of a rectangular letter U, the arms of which are about an inch apart and long enough to extend from the center of the upper lip to the crown of the head or beyond that point; opposite the supra-orbital ridge a sharp angle is formed; this angle is to permit the splint to enter the orbital cavity just beneath the orbital ridge; this angle is a means of fixation of the splint against the supra-orbital ridge and is one of the most essential features of the appliance. The lower end of the splint — i. e., the transverse portion — is carried forward, away from the lip, the distance of a half inch.



A continued narration of the case will best illustrate the application of the appliance: Having formed the wire splint to fit the head, forehead and nose of my patient it was applied to these parts; a folded piece of lintine was placed between the wire and the orbital ridge to prevent painful pressure at that point; the splint was held firmly in contact with the head with a broad strap of rubber adhesive plaster carried across the forehead and completely around the head.

The nasal bones, which could only be held in position by continuous pressure, were easily retained by pads of lintine placed between the splint and the side of the nose. A large, strong silk suture was carried through the septum near the point of the nose, the nose was pulled down by tying the ligature to the transverse wire beneath. The mucous membrane and cartilage (but not the skin) of each of the alæ were pierced by similar ligatures, and when drawn down to their proper positions the ligatures were fastened to the wire beneath.

The result in my case was eminently satisfactory though not perfection and was far better with this splint than it could have been by using any splint that has preceded it; indeed there *is* no appliance, so far as I can learn, that *can* perform the office of this.

I have recently added to the appliance a means of elevating depressed portions of the nose and permanently retaining them in position. It consists of a wire of spring brass, bent so as to elevate the depression to the normal position by pressing upward from the inside of the nose. The wire should be covered with soft-rubber tubing; the stiffness of the wire should ordinarily be less than that of the outside splint. Each intra-nasal wire can be firmly fixed to the lower angle of the splint by a simple mechanical arrangement. This permits the intra-nasal wire to be removed from the nose and from the splint when necessary to change its form or pressure. I have experimented with these intra-nasal attachments and believe that when properly fitted to the inner surface of the nose they will raise the depressed part and retain it in position more satisfactorily than any other device heretofore offered. The splints are manufactured by Chas. Truax & Co., 75 Wabash Avenue, Chicago.

Let me recapitulate the advantages of the appliance:

1. They are simple; the first described appliance can be made in a few minutes by any surgeon who has the wire and a pair of suitable forceps.
2. It is easily applied, remains permanently in position and permits the organ to be inspected during the progress of recovery.
3. It holds a compress firmly to the side of the nose when such are needed to correct deviations, an important matter in some cases.
4. It will draw down the point of the nose or the alæ and hold them firmly in their normal position. No other appliance for accomplishing this has heretofore been presented to our profession.
5. The intra-nasal wires, when used, remain where placed, a statement that is not true of the intra-nasal plugs ordinarily used, such as cloth-cotton, rubber tubes, etc.
6. I suggest the use of the intra-nasal splint in restoring the normal esthetic shape and overcoming the deformities of noses long previously fractured, after vicious adhesions and unions have been broken up.

DISCUSSION.

Dr. E. M. DOOLEY, Buffalo—I think, as I have served as a lay figure for the demonstration of this apparatus, it is my privilege to speak on this subject, and I would like to state for the benefit of those who have had no experience with the splint, that my experience was extremely pleasant; in other words, it was quite comfortable as long as I had it on—but whether the inside is as comfortable or not I have my doubts. But I think from my experience with broken noses, and owing to the locality in which I live I have had a great deal of experience with broken noses, and I have often been at a loss to have a splint that would do in any and all cases, and I feel very thankful to Dr. Hawes for exhibiting this splint, and I shall use it in the next case where I think it will be of service.

Dr. KIBLER, Cory, Pa.--Just one matter that occurred to me in connection with the splint, and that is—I am glad that Dr. Dooley testifies to the fact that the splint is a good one--could that part that enters the nose be made of hard rubber? It could be made more thoroughly aseptic and I believe give less danger to the mucous surfaces than you could have from the brass wire.

Dr. HAWES—It probably slipped your attention that that is covered with a soft rubber catheter.

Dr. LEMEN, Denver—As this originated in my neighborhood, Dr. Hawes being a neighbor of mine, and I was being occasionally asked to treat broken noses, he insisted that I use it, and I have used it in a number of cases and am very much pleased with its application; it holds the position of the bones perfectly. If the surgeon's apposition is properly attended to, the same is continued by the application of the splint.

Dr. COLE, Helena—It strikes me as being an extremely ingenious device. In the entire field of accidental surgery in minor matters there is nothing more troublesome, perhaps, than fracture of the nose with displacement, and to get a satisfactory result is sometimes exceedingly difficult, and if I understand rightly the application of this apparatus it should be a practical part of every surgeon's paraphernalia.

Dr. W. J. MAYO, Rochester, Minn.—I was very much interested in the splint of the Doctor, the external part I have never seen used in this connection. My brother, Dr. C. H. Mayo, has used a somewhat similar intra nasal splint in the elevation of depressed nasal fractures, and also a method of his own for the relief of sunken nose caused either by fracture or specific disease. In sunken nose he cuts obliquely through the septum and the depressed tissues behind and inside of the nose with a heavy chisel or cartilage knife, and elevating the septum introduces the splint, which allows sound union at a high level. In these cases the results have been excellent and continued so. The bevel of the cut surface enables the sliding upward of the depressed portion. The splint used by him consists of a similar piece of brass wire bent by a single turn into a coil, the two projecting ends being introduced into the nostrils, one along the floor, the other sprung up beneath the depression; the tension of the spring thus formed gives the necessary upward curve, one splint thus constructed and covered with iodoform gauze being introduced into each side and left for a number of days.

Dr. BRYANT, Omaha—I think this invention of Dr. Hawes for holding down the nose after an injury, not only the best splint I have seen, but the only one. I have never seen one for this particular purpose. The difficulty in a majority of the cases where injury to the nose has been received, is not to hold the nose down, but to raise it up—probably 90 per cent. or more would have a depressed nose, instead of an elevated nose; but this seems to be an all round splint, not only to hold it down but to elevate it. If I were to criticise this I think it would be in the portion that enters the nostril, and that criticism is not anything of value, it simply would be this: In many cases, make it larger in order to keep it in, and that could be done by winding the copper with thread or string and then using soft rubber over that. I believe soft rubber is the best thing to prevent irritation of the mucous membrane, and I think this [indicating] might be uncomfortable after using it any length of time—that is, I think it would.

Dr. HAWES—In making some remarks upon the comments that have been made I come first to the comment that the inside appliance is uncomfortable. Any man that has ever had any experience knows that nothing is very comfortable in the nose; whenever you push up there a lot of cotton or cloth it is uncomfortable—but that has hardly ever been an objection during the years it has been practiced; it would be customary to use a wad of cotton, which is a thousand times more uncom- table than the other, which is much more efficient. One of e other criticisms was on account of using a hard brass sub- that was liable to corrode. That I reply to with the statement that in the paper it was stated it should be covered with a soft rubber catheter. I want to call attention to another fact, that I have presented to you two splints, the second is an outgrowth of the first; the second can be used for all purposes that the first was used for, the first can not be used for the purpose for which the second is. The first is intended to draw down the nose when it has been drawn upward; the second is intended to raise the nose from the inside, which is wholly outside of the field intended as the proper field of the first. Dr. Mayo speaks of a method which I was not aware of; I have never seen it mentioned in the books. It is very evidently an excellent method of raising these depressed noses. This one of mine, while I have never had an opportunity to raise depressed noses, I have no doubt will do exactly what the other one does. The person who is using the splint should have some knowledge of the anatomic form of the inside of the nose, and should then bend his wires so that they should fit that form in particular, and raise the nose to its normal and esthetic position. The comment of Dr. Bryant that it should be larger can be very easily attained by using a larger catheter instead of the little catheter—I peeled off and threw away the rubber that I had on the outside when I began to talk, to show you the wire. By using the larger catheter you can adapt it on the inside to a nose of any size that you desire. Another of our members inquires. Where can I get these splints? I have stated in the paper that all you have to do is to get a piece of wire and a pair of pincers. If you want something better you might go down to any of the instrument makers, or even to the common tinsmith, and by giving your ideas, you might get it made in a very few minutes—if you go to the instrument maker it will cost you a dollar and a half; if you go to the tinsmith it will cost you ten cents. That is all.

THE PRESIDENT—Can the surgeon readily make that second splint?

Dr. HAWES—I made one; I am not a tinker or son of a tinker, but I made one in a bungling sort of way. This I took to the tinker and asked him to make it, and he made it rather better, shapelier far than I can; you would have to take that second one to the tinker or tinsmith or instrument maker. I do not think it is wholly perfect, but that it is an embryo of a valuable instrument, a valuable appliance.

Dr. REINEKING, Sheboygan, Wis.—I would like to make a suggestion in regard to the enlargement of the intranasal portion. I think that can be done and made comfortable by winding around absorbent cotton and dipping that in melted parafin which can be impregnated with an antiseptic solution; a backing of cotton cloth can be built up on the intranasal splint; the parafin is hard enough to make sufficient pressure.

Dr. HARNDEN, Waverly, N.Y.—I think it would be in order that a vote of thanks of this Academy be extended to the Doctor for bringing to our attention the valuable instrument.

Motion seconded and unanimously carried.

REMARKS ON THE TREATMENT OF FRACTURES.

Made at the Third Annual Meeting of the American Academy of Railway Surgeons, held at Chicago, Ill., Sept. 23, 24, 25, 1896.

BY R. ORTEGA, M.D.

CHIEF SURGEON TO THE MEXICAN INTERNATIONAL RAILWAY,
CIUDAD PORFIRIO DIAZ, MEXICO.

I want to talk about a treatment or practice which gives the patient entire relief at once from pain and puts him in good condition for work as soon as the fracture is solid. As soon as a patient breaks a bone I make massage from the lower part of the fractured limb to the upper part; we commence to do the massage very gently just on the skin, with anything, oil, or soap and water, salve or vaselin to allow the hand to rub without hurting. Ten or fifteen minutes afterward we do the massage on the muscles, always from the end of the member up, never making pressure; in ten or fifteen minutes after the pain is gone and we can reduce the fracture without chloroform or pain. As soon as the fracture is reduced we roll it in a simple flannel bandage, from the end of the member upward; if it is in the arm we put the arm in a simple handkerchief from the neck; if it is in the upper arm, the weight of the arm is enough to keep the fracture in good position. And the next day we do the same treatment, a little massage and a little movement in all the joints of the broken limb. I have done this treatment for a year. I have had but few cases as my practice is very small. One boy about 18 years old, had a wheel from which he fell and broke his right arm in the middle with a compound fracture, the upper end of the humerus projecting through the skin. Dr. Lord reduced this fracture, put on a good dressing and an apparatus, and he called the next day to see the patient; the patient wanted to cross the river. I saw the boy with Dr. Lord; we took off the apparatus, the wound was in good condition, aseptic because the doctor had put a very nice and good dressing on. I told him I was going to take off the apparatus as soon as I brought the boy over the river. I did so and then applied a bandage, and made motion in the elbow and other joints and in fifteen days this boy was at work as before the injury. There was a compound fracture of the humerus and simple fracture of the ulna, and in fifteen days later the boy recovered and worked as before, all the bones completely healed. I had one day two cases: one a small boy about 6 years old, broke the humerus of the right arm, not a compound fracture; I applied massage at once, and in ten days this little boy climbed trees and did almost everything. The same day in the shop, a workman broke his humerus in the middle, and the fracture was displaced, I did massage and put the fracture in position and rolled it in a bandage, and I left this arm without an operation; I did massage every day and about 20 days afterward this patient was in good condition. I do not remember the details of other cases, but I want to call your attention to this treatment. It gives a little more trouble to the doctor but that does not count; the patient does not suffer and is able to work very soon. My company does not give wages to people when they are sick and I think this treatment is very good because it does not keep patients two or three months without working; they can go to work in 15 or 20 days.

SURGERY ONE HUNDRED YEARS AGO.

AN HISTORICAL STUDY

BY DR. GEORGE FISCHER.

DEDICATED TO THE GERMAN SURGICAL ASSOCIATION.

TRANSLATED FOR THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION BY CARL H. VON KLEIN, A.M., M.D.

VIII.—PROFESSORS OF SURGERY AND PRACTICAL SURGEONS (WUNDAERZTE).

(*Continued from page 29.*)

In October, 1765, two Germans traveling for study reached Leyden together. With the greatest kindness, their celebrated countryman, Albinus (born in Frankfort on the Oder), whose anatomic works and drawings surpassed anything which had hitherto been done in descriptive anatomy, opened to them his invaluable storehouse of specimens. The two young men, who here formed a bond of friendship which lasted through their whole lives, became later the best teachers of surgery, A. G. Richter and *Carl Caspar von Siebold.* The latter, who was six years the elder, was born (1736-1807) in the little town of Nidecken, where his father was a surgeon, and at the age of 16 he entered the school in Cologne, in order to study philosophy. There he made such good progress that he was enabled to take part in public disputations. In 1755 he returned to his father, who gave him instruction in surgery. When the "Seven Years' War" broke out Caspar entered the French army, which marched against the Hanoverians in Jülich. For three years he remained in the French field hospitals, where he had opportunities to perform operations. While in winter quarters he attended the lectures which were given by some French surgeons, according to official requirement. In 1760 he was stationed in Würzburg, became acquainted with the professors there, gave up his appointment and became assistant to Stang (later his father-in-law), who had been chief surgeon in Julius Hospital since 1731. Here he also attended theoretic and practical lectures for three years and then took his doctor's examination. The conferring of the degree was postponed, as the bishop-prince gave him money out of the university funds to enable him to travel. Siebold went to Paris (1763), remained there eighteen months, attaching himself chiefly to Morand, in the Invaliden Hôtel. He heard Sabatier, de la Faye, Bordenave, A. Petit and Levret, industriously practiced lithotomy on cadavers under Moreau, and visited the Hôtel Dieu. In 1765 he visited Le Cat in Rouen, and resided with him a long time in order to learn better methods in lithotomy. Then he went to London. There W. Hunter, Pringle and the operations of Pott, Bromfield and Hawkins engaged his attention for three months. From there he went to Leyden and visited Albin and Gaub. In 1766 he turned back to Würzburg, where three years later he received his degree. He assisted the professor of anatomy, surgery and obstetrics, Huber, and the chief surgeon Stang, who now retired. After their death he filled the two offices of city and country obstetrician (1779). He refused a call to Berlin as professor of surgery, and surgeon in the Charité. The battle of Würzburg, in which Archduke Charles forced the retreat of the French, brought many wounded Austrians into Julius Hospital, and these were cared for by Siebold and his sons. As a recognition of his untiring activity, Emperor Francis II raised him and his descendants to the nobility of the Holy Roman Empire (1801). Soon after the bishop-prince advanced him from private-surgeon to private-physician, and the court councillor promoted him from professor to privy-councillor. Siebold's activity in the various faculties was very extensive, yet he managed affairs with great energy. In the winter he lectured on anatomy, conducted the experiments in preparations, at first without a prosector by his side, lectured on operations and gave a course in operations. In the summer he lectured on bones and bandages. After New Year's he gave instruction to the midwives and frequently gave private lectures on the theory of obstetrics and diseases of the eye. He was also engaged in making a collection of surgical specimens and conducted the surgical clinic in Julius Hospital every day. For his relief he gave up obstetrics (1790) and had his son, J. Barthel, appointed extraordinary professor of anatomy and surgery (1797), who had had the special instruction of treating the patients in Julius Hospital with his father. When, in 1802, the government of the bishop-prince was abolished and the Bavarian kingdom set up in its place, a reorganization of the university, henceforward called Julius-Maximilian University, was effected, and the chair of anatomy was separated from that of surgery. Carl Caspar and J. Barthel were appointed professors of surgery, and the former acted as director of the anatomico-surgical institute.

With C. C. von Siebold there began for Würzburg a new and brilliant epoch, such as the university had never before experienced, insomuch that at the end of the century Würzburg was considered one of the first universities in Catholic Germany. Aside from the successes which Siebold achieved in behalf of his little fatherland through the founding of the surgical clinic, the improvement of obstetrics, through his active part in the organization of Julius-Maximilian University, and through the elevation of the surgical profession in the eyes of physicians and of the public, it was especially upon his eminent qualities as a teacher that his reputation in Germany rested. After Göttingen came Würzburg, which had the advantage of possessing over the first mentioned and over other universities, a very large and beautiful hospital—the principal school for surgeons. Siebold attracted a great number of students, among them many foreigners, and he distinguished himself before his colleagues through the fact that he trained up a large number of academic teachers from his body of assistants. Among these, besides his sons, were Professors Weidmann and Fibig in Mainz, [illegible] in

Bamberg, Brünninghausen and Hesselbach in Würzburg, Markard, Adelmann and others. Many of his countrymen considered Siebold as one of the greatest surgeons of his time, and his copper-plate portrait bore the inscription "Chirurgus inter Germanos princeps." Sometimes the reputation of an eminent man is depreciated by envy, but in this case it was exaggerated by enthusiasm. Only the crucible of time brings out the true merits, and history has moderated that judgment. Doubtless Siebold was one of the best surgeons of his time, but he had no very great scientific importance; surgery was not advanced by him. He was a good operator and was honest enough to regret that he had never become skilled in cutting with his left hand, and he advised his pupils to early learn to cut and saw with the left hand, in the dissecting room. For the first time in Germany (1778) he performed the synchondrotomy with success, for which the *Académie de Chirurgie* in Paris made him one of its members. He also several times ventured upon the extirpation of the *scirrhous parotis*, yet he adhered to the principle of Celsus against too great a readiness to operate: Never lay a hand on one whom thou canst not save, then thou wilt not be thought the murderer of those whom thou couldst not save.

We can get a clearer picture of Siebold's intellectual bent if we allow him to speak for himself. After he had reviewed, in the preface to his surgical day-book, the difficulties with which he at first had to contend in Würzburg in order to elevate surgery and the profession of the surgeon, he says: "Often my labors were not entirely unrewarded, but I have found the greatest reward within myself, and in the abiding consciousness that I have neither utilized nor called forth all that might be achieved in the realm of the profession, in its extreme limits. . . . As chief surgeon of Julius Hospital I was in a position to practice the profession to my heart's desire, and to put its principles into the completest execution. I always consider the hours which I devote to visits in this place as the best and most pleasant of the whole day. . . . Almost from the first hour of the practice of my chosen profession I have taken the opportunity daily write down faithfully and circumstantially all or early all the cases which have come before me, together with their progress and result, because I would be so completely absorbed in many cases that conversation with colleagues of sterling worth was impossible to me. Literary work was not at that time a part of my intentions, and indeed could hardly have been so, as I was expected to remedy ills with the knife and not with the pen. This note book I kept up every day, and I do not know whether one of my natural functions or the keeping of this so-called day-book is now the more natural to me. I noticed at the same time a subtle influence upon my own development, and encouraged my young colleagues to undertake a like system with their cases, for the sake of their own progress and for the refining of their powers of observation, which demand training just as much as any other of the faculties. . . . Many observations I turned to good account in disputations . . . but in the eyes of my friends I was no writer. At times I indulged in enthusiasm: I had illusions, and saw in the most vivid colors huge volumes before me, with which I should shine in the world of letters; many a time I wrote half the night (for the days left me no time). . . . Sometimes all desire for the life of a writer forsook me; at times the greatest indifference overcame me; such was my fate for twelve years, in which sometimes I would be a writer, again I would not. A few friends, indeed, addressed themselves to my conscience, and said that the "not yet writer" committed a sin of omission which I (they flattered me!) with my scholarly career took to heart. . . . My friends were not entirely wrong; I will resolve to seat myself and sharpen my pen for a literary life. I resolved, yet long remained undecided, for all kinds of difficulties confronted me; the greatest was my ever-increasing practice. Then I found that it is not so easy to establish one's self as a writer; it is one thing to settle a matter with the knife and quite another to do so with the pen. . . . I finally resolved to all earnestness. . . . In my fifty-fifth year I entered upon my literary career. But once more (rief ich ihm unter der Hausthure), supposing the effort should not meet with applause or should fail. My friends vouchsafed me scarcely a glance, I was obliged to pluck him by the coat and extort an answer from him. 'How can you have any doubt of it?' said he, 'your business is truth, and it is the business of humanity.' . . . My readers will see that to me, or rather to my temperament, which I can not change, it is a hard matter to become an author, a career upon which many cheerfully venture before they know anything, whereon they can write, and carry a pencil in their trousers pocket, and suppose themselves to be writers before they even have at hand material enough for a single letter. . . . I began to break off many pleasures, to sacrifice myself, and gradually to become accustomed to sitting, in the face of former habits of long duration. Now the time for action had come. . . . But from all this my readers will see that I was not born a writer. . . . I have often observed in young surgeons, and, if I may be permitted to say so, also in older ones, that the most ordinary things, or rather their proper handling, seemed the greatest rarity. Accordingly I consider the most valuable those of my notes of which the intelligent reader can make the most use. It is not my purpose to dispense so-called observationes rariores, yet I will let such go with the rest; let anyone use them who can. I have employed the chronological order, and a kind of disorderly order, which also appears in other writings of the kind which have passed unscathed through the hands of good critics. . . . I lead my friends through a blossoming meadow; let every one pluck and read and carry away what pleases him, and leave the tree and shrub standing; that which appears to him unfruitful perhaps he may take to his colleague. . . . Pardon me, worthy masters, that I can not appear in your uniform; I have the misfortune to be a man who finds himself continually on the road in behalf of his science and of mankind, and one who can not possibly find time to change his traveling clothes in order to present himself in a literary garb. . . . My intention is to use and not to publish. . . . Elegance of diction is no part of my business, and still less is literary adornment, yet I have not been careless in seeking for the greatest possible accuracy of expression. Should many an inaccuracy have crept in, I request that the honorable police court of the language, charged with the keeping of the purity of the *German* tongue, do not exceed the bounds of its jurisdiction, and for the sake of a small twig uproot the whole tree. What would be said of such a forester? . . . I believe I have observed a certain kind of punctuality in the applying of the bandages and the use of the instrument, even in cases of minor surgery, so-called against my comprehension and wish, for I consider such just as little beneath the dignity of a surgeon as the greatest and most celebrated operation, because in all cases a man can be a great or a small surgeon. Truth, I repeat, is the stamp which I wish above everything to incorporate in my observations; I have accordingly not only related my successful cases, but even my mistakes, and have acknowledged myself as the author of a mistake when I either misunderstood the language of nature or anticipated it in too hasty a manner, and all with the best intentions! I have also striven, as appears to me to be the duty of an honorable man, to present all sides, even at the expense of my own vanity. . . . I make the honest confession to my readers that I have felt just as much delight when I could endorse an old method for the benefit of the profession as when I saw something new gained for it. I have, therefore, never affected a love for innovation. I have cheerfully been the last to take up a new theory, and have accordingly gained thereby. . . . . . So I confess that in the confirmation of an old principle throughout a number of uniform experiences I count it as much to my credit as in the discovery of a new and unheard of case, which is often the result of accident, and in need of further confirmation. Yet my readers will find, least of all, that I condemn what is new, for I believe myself to have kept up with the spirit of the times. Only in difficult operations do I follow the old methods to which I have been most accustomed from the time of my first instruction. For instance, I have never attempted a lithotomy in any other way than according to the method of my teacher and guide, Le Cat. . . . I have preferred a safe cure, approved after long trial, to any unsafe attempt, even if its color of novelty was ever so alluring. . . . I will now see how it is to be an author. If I meet with misfortune my friends who persuaded me to this step will have to answer for it. Literary vanity and fondness for writing were never, I repeat, the happiness of my life. But if success comes, and this effort results prosperously, then a continuation will soon follow. . . . But nothing can come of it if my critics go too far."

A number of Latin dissertations preceded his masterwork, "The Surgical Daybook," (1792). In this there are a hundred case reports, which cover a period of one year, and are given in chronological order; brief, clear and sharply outlined pictures, unfortunately without the diagnosis in every case. They show an experienced practitioner, but very little science. Siebold wrote on lithotomy (1778), on the cutting of the os pubis (1778), castration (1802) and several lesser articles for academies and periodicals.

Carl Caspar was the father of an illustrious family in medicine. Four sons devoted themselves to it; the eldest, George Christopher (died 1798) received from his father the professorship of obstetrics in Würzburg; the second son, Damian, was a medical counsellor; the youngest, Adam Elias (died 1828), after his brother's death became professor of obstetrics and teacher of midwives. He founded the lying-in hospital in Würzburg and also in Berlin, whither he was called. The third son, *John Barthol von Siebold* (1774–1814) after his studies in Würzburg and Jena, became assistant to his father, as has been mentioned before. He gave anatomic demonstrations, lectured on osteology and bandaging, and in every semester taught theoretic surgery. He prided himself on being the first of the Würzburg professors to lecture on pathologic anatomy. He was appointed ordinary professor of surgery, and, upon the death of his father. took the position of chief-surgeon in Julius Hospital, The hospital fever, which during the war proved fatal to so many physicians (eighteen in the Grand-Duchy of Würzburg alone), caused his death. Barthol's scientific accomplishment, like that of his father, is of minor importance, yet he possessed a talent for teaching and skill in operating, kept a day-book, and published annual reviews in the *Würzburger Gelehrte Anzeigen*. Some of his notes were scattered through the dissertations of his pupils, and in different journals. He established (1805) a new periodical, the *Chiron*, and took charge of a collection of rare surgical observations.

At the same time, in Würzburg lived *H. J. Brünninghausen*, one of the best pupils of C. C. von Siebold and A. G. Richter. He was general staff-surgeon of Würzburg, professor and chief district-surgeon; he gained much credit for his treatment of fractures of the lower limbs (1789) and of the collar-bone (1791), invented a machine for club foot and an artificial foot for use after the amputation of the lower limb. The Würzburg collection was greatly enriched through him. At the same time Würzburg possessed *Friedrich C. Hesselbach* (1759–1816), an able demonstrator who turned his attention especially to surgical anatomy. Untiringly active in his lectures and in the conduct of pathologic dissections, he amplified the anatomic cabinet in such measure, that under his direction it came to possess 680 dried specimens, and 501 in alcohol. In consideration of this service, the faculty made him a Doctor. It is to him that we owe the first distinction between the two forms of inguinal rupture, which he accurately described together with thigh-rupture (1806), and a statement of the various positions of the Art. epigastrica in internal and external rupture (1815). He also distinguished the anterior inguinal ring from the posterior, and showed that both were ends of the inguinal canal. The value of these researches is only appreciated when one considers that in Heister's time, the difference between inguinal and crural rupture was not at all understood, and that even A. G. Richter had no conception of the anatomy of the inguinal canal.

Surgery in Berlin, in the second half of the century, was chiefly represented by the military physicians Bilguer, Schmucker, Theden and Mursinna, to whom, as the best physicians of their time, we will later devote a special chapter. *J. Frederick Henckel* (1712–1779) lived in Berlin, first as military; later as civil surgeon. Born in Prussian Holland, he studied surgery, first with his father, then with surgeons in Königsberg and Danzig. In 1731 he went to Berlin to visit the colleges and the Charité under Eller, when he engaged to serve three years in the Kleist Infantry Regiment, as company surgeon. He became surgeon to the Potsdam Grenadiers; then was advanced to pensionary surgeon, and in 1739, King Frederick William I sent him to Paris for two years, where he studied under le Dran, Ferrein, St. Yves, and became acquainted with La Peyronie, Petit and Winslow. As regimental surgeon of the prince's regiment he treated the king during his last illness, was with him at his death and present at the embalming. When Henckel returned from the first Silesian war, he held private lectures and demonstrations for students in the Royal theater, and gave courses in bandaging, which subjected him to much ill will and envy. Senff and Neubauer were at the same time exposed to similar annoyance. Receiving his doctor's degree in Frankfort (1744) he entered the second Silesian war, took part in the battles of Striegau and Sorr, and then forsook the military service in order to devote himself to study. In 1750 he became a member of the Paris Académie de Chirurgie and was appointed professor of surgery and midwifery at the Collegium Chirurgicum and surgeon-in-chief in the Charité. Henckel was very industrious. He encouraged the publication of practical experiences, insisted upon autopsy, inspected surgical preparations himself, and showed so much enthusiasm that he offered from his own pocket, ten Friedrichs d'or to the scholar who should write the best chirurgia medica, Henckel himself being the judge. Unfortunately, he was hampered by the want of a good education, as is shown by his dispute with A. G. Richter, and his abuse of other critics. He opened his literary career with a collection of medical and surgical treatises (8 St. 1747 –63). His most important work is, "Directions for better surgical bandaging" (with fourteen tables and 102 copper plates, 1756), which ran through many editions, and was indeed, for half a century, the most popular work of its kind in Germany, in so much that seventy-three years after its appearance, it was re-edited by Dieffenbach. Henckel decided, when the suggestion had been made to him after he had lectured on bandaging for twelve years, to re-edit Bass's work on bandaging. According to his own confession he essentially followed this, and indeed, like Heister, frequently copied it word for word. It is seldom that the development of a science can be followed so clearly as that of bandaging. Dieffenbach revised Henckel, Henckel based his work on Bass, and Bass on Verduc, who wrote in the year 1703, covering a period of twenty-six years. Henckel's works, indeed, suffered from a superfluity of obsolete bandages, but what he wrote was clear. brief and practical. His treatise on fractures and dislocations (1759) is worthless. His treatises on surgical operations (8 St. 1770 –76) were cursory and without importance, written without order or consistency, and were completely exploded by Richter's critique. In his later medical and surgical sketches (two collections, 1769–72) there were good notes from the Charité and also in his last work, the medical and surgical notes (1779) which were for the most part read in the Royal Academy of Sciences and Fine Arts in Berlin. Henckel was also an active writer on obstetrics and was the first German to perform the Cæsarian section in the linea alba (1769), which operation was, moreover, successful.

Among other Berlin civil surgeons, Professor *A. Frederick Pallas* (1731–1812), son of Simon Pallas, made himself known through his "Surgery" (1764); for the most part he was faithful to the doctrines of his time, but was so superficial that. for example, he devoted only thirty pages, in the tenth part of his book, to the discussion of wounds. His colleague, *J. G. Zenker* (1759–1807), was professor of surgery in Collegium Medicum Chirurgicum and was famous as a good teacher and operator. He wrote little: his most important production dealt with the injection of equal parts of water and wine in cases of hydrocele (Theden's Neuen Bemerkungen," 3 Th., 1795).

Surgery was taught at the Universities of Jena and Halle by a very active man and industrious writer, *J. Christian von Loder* (1753–1832). Born in Riga, he studied in Göttingen and was there made doctor by his future father-in-law, A. G. Richter, as "a young scholar of no ordinary promise." In the following year (1778) he became ordinary professor of anatomy and surgery and director for the lying-in-hospital in Jena, where we have already had occasion to visit him in his medico-surgical institute. He taught here for twenty-five years. He gave up his position as body physician and privy councilor in Saxe-Weimar, and went to Halle (1803–1810) and from there to Moscow, as professor of anatomy and surgery, where he was ennobled. In the war of 1812 he conducted several large field hospitals built by him and took an active part in the establishment of the great military hospital at Moscow, of which he was for three years the head. In 1819 a new anatomic amphitheater was built there according to his plans. He died two years after the outbreak of Asiatic cholera in Moscow in the midst of his activity. Loder was more of an anatomist than a surgeon. As such he recognized, as did his father-in-law, that the true value of a surgeon lay, not alone in skill in operating, but above all in the knowedge of so-called medical surgery, by which a man learns to avoid operations. Among his works should be mentioned in this place his medico-surgical notes made in the hospital in Jena (I. 1794), in which he, among other things, appeared as a spirited champion of the Alanson method of amputation. Soon after Richter had called him to act as co-editor of the *Chirurgische Bibliothek* he began to publish (1797) his own journal of surgery, obstetrics and medical jurisprudence. The "Elements of Surgery" (1799), so popular at that time for use in lectures, must not be left unmentioned. An early death claimed a very hopeful student of Loder, namely *J. V. H. Kohler*. He had accompanied his teacher in scientific journeys through France, England and Holland, and was assistant superintendent of the lying-in house and the hospital in Jena. When he died, in his 22d year, he was court surgeon and privat docent (1796), and had already published a good introductory work on bandaging and described a part of Loder's physiologic and pathologic specimens.

Two students of Richter—*Just. Arnemann* (1763–1806) and Wardenburg—lived with him in Göttingen. The former came from Lüneburg and at first studied philosophy then later medicine in Göttingen. That university appointed him a professor in 1787 and he went on a two years' journey to Berlin, Vienna, Pavia, Paris and London. The Society of Sciences in Manchester and Joseph's Academy in Vienna, both made him an honorary member. After fifteen years' residence Arnemann left Göttingen, whether on account of Himly who had just been called, or Langenbeck who had just settled there, is unknown. He moved to Hamburg, where he soon took up his residence. Arnemann was full of zeal for his science. Aside from an essay on fatty oils, which won a second prize during his student days, he conducted very successfully an experiment in regenerating living animals. In his first book, devoted to the regeneration of the nerves (1786), after many experiments on dogs, rabbits and goats, he believed he had proven beyond doubt the impossibility of regeneration and held the former demonstrations as untrustworthy and incomplete. The nerve sheaths were said to extend on both sides over the *marrow* extravasation and when a firm junction was formed, which he found only in the nerves of the forelegs, in the cruralis and tibialis, the adjacent cellular tissue contributed most largely thereto. In the second volume followed experiments with the brain and spinal column. Arnemann's relation to Richter appears to have been unfriendly from the beginning; this is shown by the fact that besides founding a clinic of his own in Göttingen, when a very young professor he ventured to publish a *Bibliothek für Chirurgie und Praktische Medicin* (Library of surgery and practical medicine) in 1790, at a time when Richter's *Bibliothek* was most popular. He did not once mention Richter's work and thought that in spite of all the journals a new periodical would not be entirely superfluous, because all the others, as everyone complained, were considered either much too lengthy or too brief for practitioners. It was also a fact that the student never contended against his teacher, but almost never quoted him or praised his work. His *Bibliothek* was discontinued after three numbers. Soon afterward a new experiment was made with the *Magazine for Surgical Science* (1797). Not satisfied, the undismayed editor founded for a second time a *Bibliothek* for medicine, surgery and obstetrics (1799) which was chiefly to give general critical reviews from the mass of special periodicals. It lived but two years, while the *Magazine* held out until Arnemann's departure from Göttingen. We have besides, from his pen, a discussion of surgical instruments; a practical treatise on medicine, a treatise on surgical remedies, a hand book of practical medicine and finally a system of surgery (2 Bde., 1798–1801). Like Richter, Arnemann also protested against every one-sided system of medicine; the best operations always seemed to him a reproach to the science. As progress in surgery stands in inverse proportion to the necessity for operations, so the unusualness of an observation is inversely as its value.

His colleague, *G. Wardenburg* (176?–1804), born in Varel, studied in Göttingen, then became Richter's assistant, and went for a year and a half to Paris, where he made friends with Bichat. Appointed professor extraordinary in 1800, he remained in Göttingen only three years, leaving there to become body-physician to Prince Sanguszko in Volhynien. His translation (1799) of the surgical inaccuracies of Desault, published by Bichat, made the principles of the great French surgeon generally known in Germany; that is his service. His letters ("Letters of a Physician written in Paris, and with the French Army, from May 1796 to November 1797;" 2 Bde., Göttingen, 1799) are very interesting, giving a glimpse of French surgery. *Christian Frederick Michaelis* (1754–1814) was born in Göttingen. He studied under Richter and afterward in Strassburg, Paris and London. When the hostilities broke out in North America he became general staff physician in the Hessian corps stationed there in 1779. After the war (1783) he received the professorship of medicine in the Colleg. Carol. in Cassel, and three years later accepted the same position in Marburg. His doctor's dissertation (de angina polyposa sive membranacea, 1778) was the first detailed work in Germany which recommended tracheotomy in croup. He gives an especially interesting account of J. Hunter's experiments during his own stay in London in regeneration of nerves, and asserts that not only severed nerves but even large pieces cut from a nerve could, after a few weeks, be made to grow together through simple cellular tissue or real nerve substance, and the grafted piece would again exhibit motion and feeling. ("Richter's Bibl. und Brief an Peter Camper.") Arnemann disagreed with this view. Michaelis reported the methods of treatment of various physicians and surgeons in London and New York ("Richter's Bibl.") as Pott's results in spondylarthrocace, the use of opium in mortification, the treatment of croup among the Americans, gunshot wounds, observations during his stay with J. Hunter and the effect of common salt in internal hemorrhage. (Before 1766 Dr. Schiel had brought to Philadelphia this discovery of an Irish woman; since then common salt had become a general remedy in America for hemorrhage.) Michaelis investigated the difference between suppuration and matter allied to it, described instruments for compression of the art. pudenda comm., for injection in the tuba Eustachii, to check hemorrhages of the art. epigastrica, tourniquet for art. subclavia, etc. ("Progr. de instr. quib. chir. Marburg," 1801.)

There is great temptation to linger over the works of C. J. M. Langenbeck in Göttingen and B. N. G. Schreger in Erlangen, following after A. G. Richter, the most illustrious of German surgeons, but, lest we overstep too far the limits of our work, we must pass them both, since their activity fall entirely within the century.

The other professors of surgery in Germany were quite unimportant. Rougemont in Bonn, through his *Bibliothèque de Chirurgie du Nord*, made the French acquainted with the best German works. The Erlangen anatomist, *Isenflamm*, wrote on diseases of the bones; *Weidmann* in Mainz on necrosis and declared that necrosis is an exostosis, which should be treated not with corrosive but with mollifying remedies; he also opposed the abuse of cutting off gangrenous bones with hot iron, which was then practiced. *Metzger* of Königsberg had for twelve years collected material for his handbook of surgery, but its excessive brevity and superficiality rendered it worthless; his system of medical jurisprudence received greater applause. In Brunswick *Sommer* instituted collections of the choicest and newest works for surgeons, in which he included the best writings of foreigners, translated into German; his great industry resulted in twenty-seven volumes within sixteen years. Emmerich's Academy in Erfurt had a demonstrator, *Löber*, whose elements of the science of surgery was even at that time abandoned as one of the most transient of compilations and completely useless.

Kurt Sprengel, who was professor in Halle from 1789, deserves especial credit for his historical studies. A man of the widest learning, a general historian in the best sense of the term, who was equally proficient in the ancient and the modern languages, he wrote a history of surgery and operations (1805) which, in spite of many one-sided presentations, has not yet been superseded.

Ernest Platner, principally known as an anthropologist and a champion of Stahl's system, and whose opinions on medical jurisprudence were of great value, wrote appendices to his father's "Surgery" (1776), based on a masterly knowledge of literature and so excellently gotten up that one must regret that Platner could not have chosen the career of a practical surgeon. When he said that a practical surgeon would consider one single cure of more value than this whole book, by reason of his literary studies—a view which he would endorse if he were a practitioner—he only reflected the low state of the culture of his countrymen, and the often falsely understood judgment of his best contemporaries. He translated le Dran's and Morand's surgical writings.

The number of *practitioners* who distinguished themselves in surgery, whether physicians or surgeons by profession, is exceedingly small; and yet what little good was accomplished in German surgery a hundred years ago is due to some of them. Among the results are the tenotomy of Thilenius; Brückner's mechanical compression in case of aneurysm; Vogel's resections and Eckoldt's esophagotomy. That was real progress, of which many German professors of surgery could not boast at all; and if those achievements did not receive due honor at that time it was chiefly because of the meager education of the people. The name of the modest city and district physician of Lauterbach, *Moritz Gerhard Thilenius* (1745–1809), will never be forgotten in German surgery. Although a physician, yet it was he who for the first time, on March 26, 1784, in a case of club foot, had the surgeon Lorenz cut through the skin and the tendon of Achilles, thereby accomplishing a cure. The case made no stir at that time. Richter himself included it in his *Bibliothek*, with other notes of the author concerning a comb (Med. u. chir. Bemerkungen," 1789). *August Brückner*, who was a court physician, died in Gotha (1791) in his twenty-eighth year, had a similar experience. He was the first to accomplish a cure of a true case of aneurysm (art. poplitea) by indirect compression; besides this, he invented a ring tourniquet, and was fully aware that this treatment was the principal remedy (Loder's *Journal*, 1797, I, 248). This observation was also forgotten and modern surgery has yet made little use of the opinions and work of Brückner. He was one of the first in Germany to devote himself to the treatment of club foot. *J. A. Ehrlich* (born 1760) was eminent in Leipzig as an intelligent surgeon with thorough knowledge and operative skill; he was sent upon journeys by the magistrate of that city and later took part in the war and published his surgical notes (2 Th., 1795–1815). In an interesting manner he relates what he had seen in London with Hunter, Earle, Cline, Wathen, Abernethy and others. With him in Leipzig lived *J. G. Eckoldt* (1774–1828), whose name is known to this day through an instrument invented by him for the extraction of foreign bodies from the esophagus, and also through his method of esophagotomy ("Concerning the Extraction of Foreign Bodies from the Esophagus and Windpipe," 1799). *A. Frederick Vogel* (1746–1785) in Lubeck was a good surgeon who, from Richter's school, went upon a three years' journey through Germany, France and England at the expense of the senate and then published his surgical observations (1778–80), which were written with great clearness. He earnestly defended the ligature for the stoppage of blood-flow, therein opposing Agaricus, and was one of the first German surgeons who made resections. The Saxon surgeon, *L. E. Schneider*, in Mitweyda, wrote twelve volumes ("Surgical History, with Theoretical and Practical Comments," 1762–88), containing quite interesting cases, with useless comments and in frightful German. *J. Christian Jäger* lived in Frankfort-on-the-Main, as jury surgeon, after he had completed his studies in various barber shops, and had been employed in Bremen and Hamburg; he left to posterity five volumes of practical surgical precautions (1788–97). Like him *G. H. Fielitz* was the son of a surgeon who, after attending the surgical school in Dresden, had been established since 1773 as city surgeon, in Lukau in Niederlausitz, and contributed various notes to Richter's *Bibliothek*. He paid great attention to all kinds of plans for furnishing the state better surgeons and midwives. *J. Frederick Bottcher*, a practical physician in Berlin, wrote the first complete work since Petit's time on bone diseases, and also a work on selection of surgical bandages (1795), in which only the most necessary were recommended. *Hofer* in Dillingen produced a similar work ("Bandagenlehre," 1790). The Saxon mining surgeon, *J. G. Bernstein*, was also an industrious writer known through a very popular, alphabetically arranged, handbook for surgeons (4 Bd. 1790), a history of surgery and works on luxations, fractures and bandaging. There are a few other physicians and surgeons whom we will meet later in special surgical diseases: *Hagedorn* in Dessau, *Ficker* in Paderborn, the dentist *Serre* in Vienna, later in Berlin, *Lange* in Luneburg, *Greding* in Waldheim, and others.

Among oculists in the second half of the last century, we have already mentioned A. G. Richter as the founder of ophthalmology. In this department of science, as in surgery, he gathered the seed in foreign lands and planted it in German soil. Until then the principles of Boerhaave had prevailed but they were now broadened in all directions; indeed, for a quarter of a century, Richter gave to ophthalmology its specially characteristic type. *Joseph Barth* (1745–1818), who has the honor of having introduced ophthalmology into Austria, trained himself independently of Richter; since that time this science has been fostered with great care in the Vienna school. Barth was born in La Valletta in Malta, and studied surgery there and afterward in Rome, and was introduced to Störk and Leber in Vienna. Ophthalmology could hardly be said to exist in Austria at that time. Rich men suffering from cataract went to Paris to be operated on, or sent there for an operator. Barth devoted his leisure hours to this science and in the sojourn in Vienna of the celebrated French oculist Wenzel, who, upon van Swieten's invitation gave private lectures there, he found an opportunity to make himself thoroughly acquainted with the technique of operations on the eye. His first experiments as a practicing oculist, were attended with so happy results that in 1773, in recognition of his special skill in treating diseases of the eye, and in higher anatomy, Maria Theresa appointed him public teacher of ophthalmology with a salary of 800 guilders. He took the place of professor of anatomy and assumed the duty, connected with this office, of caring for the anatomic specimens presented by van Swieten. In 1774 he became ordinary professor of anatomy and ophthalmology, with a salary of 1,500 guilders, which was soon increased to 2,000 guilders. He established a private sanitarium for his ophthalmic patients. When the General Hospital was founded he was given two wards, in which during May and June he operated upon poor patients with cataract who, through an advertisement in the Vienna newspaper, were invited to Vienna from all the provinces of the empire. Emperor Joseph, whom he successfully treated in a dangerous disease of the eyes, was personally attached to him and appointed him imperial court oculist. In 1786 he accepted the chair of physiology. His anatomic work expanded in a brilliant manner when he received the means to build in the new university an anatomic amphitheater for three hundred students; the state bought his specimens for 2,000 ducats. His activity as a practical oculist was just as marked. From far and near patients streamed into Vienna to be cured by him—the only one. His private sanitarium had long been inadequate, and the collegium, made vacant by the suppression of the Jesuits (1773), and the Spanish hospital were opened to him. In 1787 over three hundred cataract patients were operated upon.

In order to preserve his experience to the State for future times, the sick Emperor, four weeks before his death, ordered that for a salary of 1,000 guilders, Barth should instruct the two demonstrators, Ehrenritter and Adam Schmidt, in ophthalmology, for which A. G. Richter's works were taken as a basis. But he could not have possession of the money until both men should prove their skill through six successful cataract operations, a test which was brilliantly established the following year. When Joseph II. died, Barth's love for public activity weakened, with a stain upon it; in 1791 he had himself pensioned. He now gave himself up to the study of antiques, and was recognized by the greatest artists of his time as a genuine connoisseur. His collection of intaglios was unique of its kind. The malignity of public attacks upon him made him exceedingly diffident and unapproachable. Except a small treatise on cataract operations without assistance (1797), and a work on muscles, he wrote nothing. His pupil, *A. Schmidt* (1759–1809), became professor of ophthalmology and teacher of anatomy and surgery in Joseph's Academy. After the "Bibliothek," published by him and Hunczovsky, was discontinued, he and Himly, in Göttingen, founded the ophthalmological Bibliothek (3 Bde. 1802–7). His name is immortalized in music, because for a long time he treated Beethoven for deafness, who out of gratitude dedicated a great Trio to him (op. 38, 1801), and expressed the desire in his holy will and testament that after his death Schmidt would describe his sickness. A second student of Barth lived with Schmidt in Vienna, Professor *G. J. Beer* (1763–1821), who as professor, author and practitioner, contributed very considerably to the advancement of ophthalmology. Students flocked to him from all countries and there were at that time few oculists who did not have him to thank for their training. Professor *Lobstein* in Strasburg and Professor *Jung* in Marburg, are well-known; and also *Siegerist* in Gratz, *Willburg* in Gemündt, and *Hellmann*, city surgeon in Magdeburg. The last mentioned was a skilful oculist of no mean reputation; he performed fifty operations for cataract within seven years (32 successful, 10 partially so, and 8 unsuccessful. "Gray Cataract and its Extraction," 1774). While Richter was a professor in Göttingen, *Hellmann* was called to Hanover, where he operated in the presence of Zimmermann.

(To be continued.)

SOCIETY PROCEEDINGS.

New Jersey State Medical Society.

Proceedings of the one hundred and thirty-first annual meeting held in Atlantic City, June 22, 1897.

PRESIDENT T. J. SMITH, M.D., Bridgeton, called the session to order at noon. It was opened with prayer by Rev. W. M. WHITE.

The Address of Welcome was made by Mayor F. P. STORY, and after some routine business, the report of Committee on Legislative Action on Bovine Tuberculosis was read by the Chairman, Dr. J. W. STICKLER. "The number of cases of bovine tuberculosis examined since the last report is about 1,200: Tested with tuberculin, 214; condemned by the test and physical examination, 159; total sum paid for condemned animals, $3,849.74; an average of $23.57 per head, including registered." The above is quoted from the Commissioner's report. Considering the great prevalence of tuberculosis in cattle in our State, especially in the southern section, in Morris and Essex Counties, from 6 to 10 per cent., I am told by competent authority—the Commission is not accomplishing as much as the emergency demands. Again, the State Board of Health reports 3,758 deaths from consumption during the last year, which is 417 more than the average for the past eighteen years. In other words consumption causes about one-eighth of all deaths in New Jersey. It is in view of these facts that the New Jersey State Society wishes thorough work to be done by the Commission already formed, or by a commission which we as a special committee of the State Medical Society would like to form. One obstacle to the proper performance of the work of the Commission is the very small appropriation made by the legislature. It is to be hoped, however, that in time, when the great importance of the work shall be recognized, all hindrances will be removed and the State amply protected.

After a recess, Dr. WM. H. ISZARD of Camden reported on

APHORISMS IN MEDICO LEGAL TESTIMONY.

He said that an expert in medicine depended mainly upon skill and experience, An expert witness is one whose opinion in medical points is valuable for his accurate knowledge of the subject under consideration. An expert in law is one who is experienced, skilful or having peculiar knowledge of the certain subject or in certain matters, in other words, a scientific witness. Testimony is used more frequently in the Bible by writers than either in medicine or law. It is defined as evidence of a witness under oath or affirmation. All medical testimony is expert testimony in a qualified sense. Expert testimony is that which is usually denominated by the term corroborative testimony. Many lawyers object to expert testimony because so-called experts differ in opinion and statements and will endeavor to break the testimony of good medical men because of this fact. It must be admitted that such witnesses do often differ, and we find them backing their opinion in heated discussion as to the cause of disease. Thus in typhoid fever and insanity legal proceedings are instituted against a city or corporation, for providing unhealthy water; death has occurred from typhoid fever in a family. Men are found who testify that the water does contain specific germs, and thus impress the jury that the water is full of them. In the same court, the other side, by scientific testimony, prove the *contrary, viz.*, that the germs found were the effect not the cause of the disease. Both are equally honest and sincere, hence it is no wonder that lawyers who are not schooled in medical science (and few are) should attempt to prejudice the jury against the reliability of medical testimony. *Insanity:* Hamilton says, especially on the question of insanity, whether civil or criminal *cases, we are to determine the influences that may destroy* responsibility of an individual, and should always bear in mind that the offices of the physician are only those in which he is warranted in forming an opinion relative to the enfeeblement of the mind through disease. The question of law should not concern him and the courts do not permit him to express more than what he knows. He should always remember the dignity of his calling, never lose his temper, no matter what or how much he may be galled by the impertinences of counsel, who are not always gentlemen. He should never be flurried, give hurried answers, but should demand time and not allow himself to be choked off or interrupted. He should never show eagerness to testify or too much enthusiasm in the cause of the side on which he is called. Testimony should be given in a cool impartial manner. He should be on the alert and avoid being trapped by his opponent. A favorite plan with lawyers is to put a hypothetic question and demand an answer to isolated parts, possibly to get a truthful negative answer to many real elements of insanity: thus, when a man is slovenly or careless in his habits, is this a sign of insanity? An infallible sign? The reply is "No." Yet this and other indications may be an important element of mental disease. Therefore the physician should be on guard and refuse to answer, save in a qualified manner. Remember all dodges will be resorted to. Thus the physician is asked whether he has read certain works, he replies in the negative. Yet these works never existed. Avoid being drawn into a discussion on various other subjects which are foreign to the case. Refuse to answer any abstract questions not strictly medical. Do not pose as an expert in other fields. It is not wise to pose as a radical and *one of more* than ordinary ability. Do not tincture an answer with anything extraneous; the witness declares himself an agnostic, he injures the case and renders himself ridiculous. One is not warranted in ventilating, before a jury, any views that he can not maintain. A flippant witness is sure to injure his case, by trying to cause a laugh or by repartee. An old lawyer bides his time and turns his remark against him and creates an opinion not complimentary to him in the minds of the jury. In other words, thoughtless answers destroy the weight of all the sound testimony given before. Keep all the facts before you. Never attempt to give information except what is absolutely demanded. Never explain or enlarge upon something of which you know practically nothing. You may be able to theorize, but before a court you must know practically what you are saying. Called as an expert, theory amounts to nothing. You can not swear by theory. The stenographer notes the testimony, every word is recorded. It is not very complimentary when the stenographer reads his notes to the witness to have it shown that his evidence is absolutely contradictory. Learn the lesson then, be on guard. If doubt crosses your mind let the answer or evidence always be, as far as permitted by the court, given in a qualified sense. There is a growing sentiment in favor of judicially appointed medical and chemic experts. Judge Garrison of our supreme court believes there is a need of medical experts employed by the court so as to do away with the apparent discrepancies between medical experts due to answers on hypothetic questions by counsel. A bill has been introduced into the Minnesota Legislature and one in New York, bearing on this subject. The central idea is that the expert witness should be judicially selected and properly qualified and not depend upon their remuneration from one side or the other. This would be a great improvement on the present system, where medical men hire themselves to testify in criminal cases to suit counsel rather than the unfolding of the truth.

Dr. CHARLES YOUNG, Newark, reported upon

SURGERY.

He gave a brief review of the progress made during the last year. He mentioned the results obtained by Murphy in end-to end union of blood vessels. These were united by continuous suture; in one case, after five weeks, where suppuration had occurred and hemorrhage from the sloughing point, he had to ligate the artery above and below, and resect the damaged vessel; recovery occurred without, disturbance of the circulation of the limb. In another case the vessel much torn by a pistol ball, the artery was secured by a clamp and the vein sutured with excellent results; no blood escaped, and the circulation went on. He quoted a new mode of ligation so as to remove the ligature without cutting. The operator places under each tie-loop silk to be used as tractor. The first loop is designated by one simple knot; next with two knots; next with three knots; and so on. When it is desired to withdraw the ligature, that with the largest number of knots is seized and drawn upon a see-saw motion, till at last it slips away, the loop is withdrawn, and the process repeated with the loop having the next number of knots till the last and the whole is easily removed. The device is simple and far more efficient than any other known plan. Especially is it serviceable in deep seated ligatures for stumps or pedicles and after removal of abdominal tumors. Intravenous saline injections, in cases of extreme shock, had been found of great value. They give a respite from death, during which the organization may recover from the shock, or throw off septic trouble. Local anesthesia in Schleich's method was advocated for preparatory operations; the cocain solution was thrown into subcutaneous cellular tissue. Caution, however, is of great importance as when the tourniquet is removed, the cocain may suddenly be carried into the circulation and to the heart, with serious results. Loosen the tourniquet slowly, say for three or four seconds, then tighten and gradually permit the blood to resume its course. The treatment of tetanus with biniodid of mercury baths and antitoxin, had resulted in recovery. The bath should be 1 to 5000, and followed by no salivation, but great amelioration of all the symptoms. Serum therapy is still *sub judice*. Results vary. Its main utility is as a prophylactic. *Hernia cerebri:* One hundred and nine cases had been reported. The causes were various, and there was great need of prevention of sepsis. Gunshot wounds of the head and trephining had occupied much attention in surgery. The operation is indicated when there is considerable arterial hemorrhage and symptoms of lateral paralysis or spasms. Later, when fever comes on and paralysis, or the presence of the ball is known, the operation may be employed. Wounds of the air passages demand great care as to antisepsis. Chloroform may be used if necessary. We should close the wound in the air passage completely: if the wound be large, in the trachea or larynx, a tube is demanded. Silk makes the best suture for the larynx or trachea; all the sutures must be introduced before any are tied; then the posterior one tied first. Divided muscles must be sutured and when bringing the skin together correct any inversion. Drainage is generally necessary. Wounds of the heart and pericardium have been treated by exposing the site of injury by freely dividing and laying back the walls of the thorax above, so as to obtain free access to the wound of these organs. Then the large vessels above and below the wound are closed by gut, the walls replaced in position, and in certain cases good recovery occurred. Wounds of the liver demand prompt exploration. Employ laparotomy to know what the injury is and to repair it. Use blunt needles for sutures through the hepatic tissue. Tie sutures tightly but slowly. In rupture of this organ, an unusual quantity of blood has been seen to flow into the abdomen. Here flushing was carried on till the part was cleared of the blood, and fragments of liver were seen floating in it. Suture being impossible, the hemostatic effects of hot water were relied on; all foreign matter was removed by irrigation, drainage by glass tubes was employed and good recovery followed. In several cases of gastric ulcer, excellent results were obtained by laparotomy, and suturing. Perforating typhoid ulcer may be thus relieved. Of all diagnostic signs of ulcer, the most reliance can be placed upon an attack of severe continued abdominal pain with nausea and vomiting and increase of the white blood corpuscles. There are no contraindications to the operation. Lateral anastomosis by Senn's operation was mentioned as having been performed on dogs, producing complete end-to-end union. The indication in operation for appendicitis was considered. Continued frequent progressive acceleration of the pulse, in the absence of other dangerous symptoms. Local pain was valuable when sudden and with a chill. Increase of the temperature is third in importance. A gradual subsidence of these symptoms is a legitimate reason to postpone the operation. He spoke of intestinal anastomoses, etc., and then of fractures treated with the ambulatory plan. The plaster appliance enabled the patient to walk about on the sole of the apparatus. It promotes the formation of callus and even enables one to attend to business. This plan is still being improved upon. Massage and mobilization of the part are liable to cause danger as producing scanty callus. Many very interesting cases were quoted from various authors.

Dr. HENRY MITCHELL, Secretary of the State Board of Health, reported upon

STATE MEDICINE AND HYGIENE.

He said scientific investigation has been industriously pursued during the past year. We have acquired a store of new facts. Bacteriology yields many treasures to the student. Protective inoculation is destined to be successfully applied in many ways if not to all diseases. Immunity as obtained by Koch against rinderpest and diphtheria has stimulated work in this manner. Vaccine bacteriology has been worked at by several and Klein and Coplin describe small bacilli in vaccine and variolous lymph, which they think is the true bacillus of smallpox. The typhoid bacillus has not yet been found to induce the disease experimentally, but the diagnosis of this disease by observing the reaction of the addition of serum from a typhoid case to the blood, has attracted much attention, a reliable method of diagnosis although thus far not much certainty has been obtained for want of more experimentation.

The investigation in England, by the local government board, on oysters and infection from sewage, shows that the typhoid bacillus and that of cholera may live in salt water for two or three weeks and thus the oyster may be a source of contagious disease. Oysters and other shell fish from polluted beds may convey both typhoid fever and cholera. Sanitary supervision of the oyster industry is demanded and the sale of that which is doubtful should be prohibited. Formaldehyde as a disinfectant, has caused a revival of interest, among sanitarians, concerning methods of purifying premises when infected with disease. Test culture has rendered it possible for health officers to prove their work, and show the efficiency of the cleansing. Steam as a disinfectant can perhaps never be supplanted when properly applied as a germicide, but it is not always practicable. As a germicide a solution of formaldehyde is excellent; not being poisonous, capable of destroying the bacilli with great certainty it is warmly welcomed, and its use is extending with remarkable rapidity. A novel device for purifying sewage has been introduced by M. D. Cameron, Exeter, Eng., the septic tank system. Raw sewage flows into the tank, from which all light and air are excluded to favor the development of putrefactive organisms which are believed to be the cause of rapid changes in the sewage. Fermentation follows, and causes the suspended organic matter to be thrown into the solution; the overflow is odorless and comparatively clear. The effluent is still further treated by passing it through coke breeze filters, when it is discharged as a clear sparkling fluid, without smell.

The mortality among infants, during the summer of 1896, was unusually small in the cities of New Jersey, and the commonly accepted explanation is that many mothers and nurses have learned the value of pasteurization of the milk; hence we have reason to expect that infant mortality will be further decreased in the future. Applied hygiene has made gratifying progress in schools. Boston has for several years had daily medical inspections by the sanitary authorities, to check the spread of disease, especially diphtheria. The result has been so satisfactory that the measure has been adopted by the city as a regular system for promotion and protection of public health. New York City has recently adopted the same plan. All show the great value of this branch of the service. The medical inspectors of the schools report many cases of disease kept out of school. There is need of coöperation of the Boards of Education and the Health Inspectors, then, without waiting for the passage of a law such inspections can be thorough in all New Jersey. Closing of schools is undesirable and should only be resorted to to prevent the spread of infectious disease.

The Sanitary Convention of Venice, in February and March 1897, to prevent cholera from India and other eastern countries, marks a progressive step. Since 1851, the first sanitary convention, there has been a gradual yielding to the view of inspection, isolation of the sick and disinfection, as a substitution for the long and vexatious quarantine. Commercial interests always dominated in maritime quarantine and the necessity for relief to trade led to attempts in Europe to prevent the spread of infectious disease, so as to avoid this delay. In the twelfth century, the republic of Venice, after being devastated by repeated epidemics organized a system of inspection and detention of vessels from infected ports of Asia, and established a *lazaretto* to which all passengers, grew and cargo were committed. Thus began by slow degrees the maritime quarantine which has prevailed for five hundred years in the western hemisphere. The national tendency is to modify the harassing features, as advancing knowledge of disease will permit. The port of New York has kept pace with the best service abroad, and the facilities for disinfecting passengers and baggage is unsurpassed.

Measles has demanded considerable attention from health officers, because of varying views. Hitherto it has been allowed to go without isolation, hence we have reaped with exasperating regularity an epidemic every three or four years. This could be wholly prevented by isolation of the early cases. The difficulty is almost insurmountable. It is exceedingly infectious in the pre-eruptive stage, and thus persons not immune are exposed. In the prevention of tuberculosis great activity is shown everywhere. The New York Board of Health has been led to place it among the list of noticeable diseases. In our State no measures like this have yet been possible; but the people will soon demand progress in this as well as other matters: in fact we may say the demand is even in advance of the sanitary authorities. The relation between the health boards and the people is in strong contrast with the conditions existing several years ago. We believe that official inactivity is due to the inadequate supply of trained employes. Instruction is provided for every other profession, but none for sanitary officers, either by the State or private plans. Hence Boards of Health are compelled to entrust the enforcement of health laws to the unskilful. The Medical Society of New Jersey has led for one hundred and thirty years in many good works. Why not give us reform in the selection and education of health inspectors? Last year we took action which resulted in placing on a permanent basis the State Bacteriological Laboratory, and without doubt the same influence could, if exerted, establish in the State, a system for training health officers. This would give us a class of men capable of intelligently applying the arts of hygiene now being promulgated with almost daily additions.

In the evening the President delivered the annual address, his subject being "The Problem of Dependency." The address was devoted to an appeal in behalf of the insane, and the feeble-minded and the society was so impressed by his arguments that a committee was appointed to consider the subject, and granted power to act, with the view of obtaining an act of the legislature which will aid in the care of these unfortunates.

Dr. L. Faugeres Bishop of New York, then read a paper on

SOME IMPORTANT POINTS TO BE CONSIDERED IN THE TREATMENT OF ACUTE LOBAR PNEUMONIA.

He thinks we are still seeking the best method of treatment, but that there is a tendency to overfeed. It is questionable whether in the acute stages of this disease with the undoubted accompanying congestion of the abdominal organ, whether harm is not often done by stuffing the stomach with milk, to the production of large quantities of gas and upward pressure on the diaphragm. Now and then a feeble voice is raised against overfeeding, but we have learned too well the lesson of support. The lesson of feeding in other febrile diseases causes us not to consider the shortness of the attack of pneumonia. There are undoubted benefits in restricting the diet in so acute a disease. Overfeeding means a consumption of physiologic force in the digestion and assimilation of food; it means the diversion of so much energy from the repair forces of the body to the digestive forces; it means the throwing into the circulation of a quantity of crude food that must be taken care of; it means the presence in the intestinal tract of the waste matter of the food that must be gotten rid of. The patient dying in acute pneumonia does not die from a lack of more remote reserve force, such as might be produced by a system of stuffed feeding, but rather from the failure of the development, when needed, of the latent force already existing. If by a system of overfeeding, such as would produce this more remote force, part of our stock of immediately available energy is used up, more injury than good is done. It is just as if the captain of a ship with an important and pressing commission should stop to replenish coal supply on the wharf when he should be on his journey, burning the supply in his well filled bunkers. Diet should be bland and moderate in quantity. It would seem that only a misconception of the conditions of pneumonia lead to stuffing in a disease in which it is more important to discount future events. An acute delirium in an alcoholic patient, when fully developed, frequently means death. The feeble power of drugs to control this delirium short of paralyzing the patient with dangerous doses, is too well known. If at the outset of pneumonia in an alcoholic patient, we foresee that the day of delirium is bound to come, we can, by the free use of safe sedatives avoid, or at least limit, the delirium of the latter days. If such a patient, from the beginning of the disease, is brought under the influence of bromid in efficient quantities, the use of the more powerful sedatives at a later period may be avoided. After delirium is once thoroughly established bromid is a drug too mild to be useful. It should be begun at the outset, given freely so that the patient gets half an ounce to an ounce in twenty-four hours. Lives have thus been saved. The next point in this disease is the value of hydrotherapy. The great problem is the maintenance of the circulation in spite of the obstruction in the consolidated lung. We must regard the circulation as a whole, not concentrating attention upon the heart or the lung or the system, always remembering that what benefits a part benefits the whole. The stimulation of the heart and the use of vaso dilators to relieve the burden have been briefly considered. Hydrotherapy is not frequently enough employed in combatting the symptoms, prostration and blood stasis. The difficulties and prejudices to be overcome before it can be generally adopted in pneumonia are so great that it is with difficulty one undertakes to break the ground. It has been so much the property of men who have prostituted medical science to personal profit, that much of value has been lost to conservative practitioners. No one who has witnessed the splendid results of systematic cold bathing in typhoid would ever be willing to be cut off from this resource in a severe case. So in pneumonia, hydrotherapy properly adapted to the condition of the patient would reduce mortality as much as in typhoid. Its value extends far beyond the limits of mere reduction of temperature. The effect is a general tonic to the nervous system. To accomplish these results the temperature and duration of the bath must be properly adapted to the case and conditions present, but there is one element in this application that is of so much importance that we are almost tempted to alter our terms and speak of the treament as "tub-rubbing" instead of tub-bathing. While in the bath the patient must be rubbed properly on every part of the body by a number of trained attendants. Without the rubbing, the bathing in an acute disease is a fearfully dangerous procedure. The direct care of the heart is equal in importance to the attention to the delirium and the destructive forces of the high temperature. Every one who has watched a patient with pneumonia, from the onset to the termination, has felt that the heart was the organ upon which the brunt of the battle had fallen. No question is of equal importance or greater difficulty than that of heart stimulation.

We approach this problem with humility because there are so many points where definite facts are not known. The mechanism of the heart and circulation are admirably adapted to fulfill their functions. The heart has its wonderful nerve supply, both from the central nervous system and also from the ganglia within itself. The blood vessels are governed by the vasomotor system acting as a system of regulators. In health the slightest mental or physical exertion is followed by increased effort of the heart and respiration. When disease or obstruction to the circulation or breathing occurs, the heart responds by increased labor to overcome the obstruction, and the lungs work even to a greater degree. Hence the question of stimulation resolves into an inquiry as to whether we can with advantage supplement the natural stimulus. We may have unsafe stimulation and exhaust the natural resources. We can not control the action of the heart and conserve its forces to calm the stimulation of an excited nervous system and thus reserve the force required to tide over a critical period. Nutrition of the heart is also of great importance. Hence we may conserve the forces early by controlling delirium by using a proper antipyretic, but at the same time tonic bathing and such drugs as will relax general circulation and diminish hyperactivity of the heart. The aconite group affords very valuable properties. Faith in the value of hydrotherapy is more the growth of time and thought. Its literature is meager. To carry out this method requires courage, skill and apparatus. Until an antitoxin is discovered, the treatment of pneumonia must be expectant in its analysis; protect the patient from harm, and support him to resist the disease. Judgment is the great need.

Dr. EVANS of Morris Plains Insane Asylum exhibited a variety of articles taken from the stomach of a patient who, after swallowing this vast load of stones, spoons, etc., died of starvation.

The Society reassembled on Wednesday morning, and Dr. R. NEWTON COLES of Montclair read

A CRITICISM OF MODIFIED MILK AND PRESENT DAIRY METHODS.

The Doctor said that when we consider the fact that the present science of lactology, if he might coin the word, is only about twelve years old, the progress that it has made is a matter for congratulation and a promise of much better things. He greeted with approval Professor Corsi's prediction that "within ten years the discoveries in bacteriology will produce a complete revolution in almost every branch of the dairy industry."

His subject offered so many and such varied phases for discussion that he was obliged to confine his remarks to the dietetic value of milk from the clinician's standpoint. Systemic writers all agreed that cow's milk must be more or less modified before it can be used for infant food. He objected to the stand taken by some writers, that the milk of cows can be so satisfactorily modified as to make it undesirable to experiment with the milk of asses, goats or mares, and alluded to the fact that the Kurds drink mare's milk made into koumiss and that phthisis is never known among these people. He also spoke of the experiments made in Paris in 1883, in which sickly children nursed asses directly and 70 per cent. of them survived, whereas of these cases heretofore all had died.

The ass is a docile, hardy and long lived creature, and less liable to tuberculosis and similar diseases than the cow. Schwartz, who prefers goat's milk for infants' and invalids' food, was quoted, and the establishment of dairies that would furnish asses' and goats' milk as required for use was advocated. The doctor said that it is an exceedingly encouraging sign of the times that the dairymen themselves have set to work to improve their own dairy products. He believes that there is very much yet to be done, and spoke at considerable length of the poison known as tyrotoxicon, which is probably the chief cause of cholera infantum. The presence of this poison in milk is not perceptible to any of our senses. Hence its great danger. Fortunately, it will not be found in properly aerated and cooled milk. The antitoxic property of fresh milk then engaged attention, with a number of interesting observations which prove that all fresh milk has certain germicidal properties. This shows that the general assertion that milk is a perfect culture medium has several limitations. It is evidently very desirable to retain this antitoxic quality in the milk as long as possible, as it is doubtless one of the reasons that nurslings are less susceptible to infection than older children. The study of this newly opened field offers great promise to investigators. Next he considered the reaction of the milk and showed the great advantages likely to follow if dairy milk could be kept alkaline for considerable periods without the use of chemicals. He quoted Rotch, who says that ten pounds of Austrian sugar beets fed to milch cattle every day will keep the milk alkaline, and also that cattle pastured on limestone lands, or the blue-grass regions of Kentucky, will give milk that will remain alkaline for a long time.

A number of facts are given to show the exquisite sensitiveness of milk to any change in the animal's diet, surroundings, care or treatment, and particularly in the way the process of milking is carried out. As to the bacteriology of milk, the limits of this paper prevented its consideration. Two years ago over two hundred varieties of bacteria had been demonstrated in milk, and each species produced its own form of fermentation. This phase of the subject opened another important and as yet only partially explored field. The writer then quoted from Mr. Ernest Hart's recent address on the "Conveyance of Contagion by Milk" and alluded to our ignorance of some of the most important facts connected with this means of infection. He also showed that the most carefully handled and Pasteurized milk might entirely disagree with infants and quoted cases to prove his point, dwelling particularly upon the bad effects of agitation and movement of milk and also upon certain occult but as yet irremediable changes which occur in milk, merely from lapse of time, which impair its dietetic value. He dwelt upon some important facts which investigation had brought out in reference to the spread of tuberculosis among dairy cattle. Professor Bang, Dr. Theobald Smith and Dr. E. A. de Schweinitz have done much to show that tuberculosis rarely appears in small herds of cattle, and also by sterilizing the milk fed to the calves of tuberculous cows and by a strict isolation these calves will grow up non-tuberculous. The danger of tuberculous infection in neat cattle increases in geometric progression with the number of cattle kept together and the number of hours during the twenty-four in which the cattle are housed. There seems to be no reason why Alvord's excellent suggestion, not to milk cows in the stables but in an airy, light and disinfected place kept free from excrement, flies and dust, should not be generally adopted by our dairymen. The Doctor concluded his paper with the following: "Fortunately the day of rationalism in medicine has begun to dawn and the clouds of superstition and ignorance are fleeing away. Whatever unsanitary evils can be prevented by scientific knowledge and hygiene we are today struggling to get rid of. We rely less upon drugs than did our ancestors, but more upon common sense as exemplified in sanitary science. In the words of the honored secretary of the Society: 'It is only by removing or obviating the causes of disease in general that medicine will make any real advance.'"

(To be continued.)

Chicago Pathological Society.

Regular Meeting April 12, 1897.

The President, Dr. JAMES B. HERRICK, in the chair.

Dr. EMIL RIES read a paper on "Papilloma and Carcinoma of the Fallopian Tube." (See JOURNAL, Vol. 28, p. 962.)

Dr. H. A. BRENNECKE reported a case of "Measles Complicated by Diphtheritic Conjunctivitis." (See JOURNAL, Vol. 28, p. 1221.)

Dr. M. L. HARRIS read a paper on a case of "Benign Cicatricial Stricture of the Ileum. Operation, Lateral Anastomosis. Exhibition of Specimen removed five years after." (See JOURNAL p. 117.)

Dr. J. E. YOUNG presented a specimen of "Defect in the Ventricular Septum." (See JOURNAL p. 118).

Dr. EMANUEL J. SENN read a paper entitled "Inflammation of Joints in Gonorrheal Patients."

SELECTIONS.

The Administrative Treatment of Undefined Cases Certified as Scarlet Fever.—Drs. Frederick Dittmar and Brownlee, both of them formerly or at present attached to the Glasgow Health Office, report on the above subject as follows: "In this communication we intend giving an account of the management of the undefined cases admitted to the Glasgow Fever Hospital, Kennedy Street, from November, 1895, to November, 1896. Prior to the former date there was an arrangement for the special observation of cases of this nature. The hospital, which is exclusively employed for the treatment of scarlet fever, consists of fourteen wards built on the pavilion system, and has accommodation for about 320 patients. The pavilion chosen for the purpose of isolation consists of three divisions separated one from another by brick partitions which extend from floor to ceiling, while each division has a separate communication with the outside. Two of them have a capacity of 16,500 cubic feet each, and the third of 8,000 cubic feet. The last has also separate latrine accommodation and bathroom.

"The patients sent to the pavilion were of three classes: 1, cases in which the appearances on admission did not justify a positive diagnosis of scarlet fever; 2, cases where the symptoms and appearances suggested some other disease, *e.g.*, tonsillitis or non-specific erythema; and 3, cases of undoubted illness where the symptoms were obscure, but suggestive of some other infectious disease, *e.g.*, enteric fever. Cases in which some other infectious disease was frankly present were immediately transferred to the Belvidere Fever Hospital without admission to the wards.

"The two larger divisions were used for the first two classes, and the smallest division for the third class of cases. The whole pavilion was under the supervision of a very careful and experienced charge nurse whose powers of observation could be relied on, while each division had its special staff of day and night nurses. During their residence in the ward the patients were carefully observed for signs of scarlet fever, the urine being examined twice daily for albumin and evidence of desquamation carefully looked for. As soon as desquamation became definite or scarlet fever complications showed themselves the patient was transferred to a scarlet fever ward, where he completed the statutory period of eight weeks in hospital. Cases which did not turn out to be scarlet fever were kept in the isolation ward for a period varying with the nature of the case, but as a rule were not dismissed under four weeks, which we considered long enough for any such definite evidence as desquamation or nephritis to develop. None of the cases dismissed from the isolation ward were sent back to hospital with evidences of scarlet fever. The main objection which we have heard raised against the kind of arrangement adopted by us is that now and again patients who ultimately prove to have scarlet fever are mixed with those who do not, and thus may infect the others. Our experience seems to show that this fear is more or less baseless, as no case of scarlet fever occurred in the isolation ward. We tried to minimize the risk of infection by putting the patients at as great a distance from one another as possible and allowing at least 4,000 cubic feet of air space to each. We also cautioned the nurses to take special care when attending a patient the subject of any inflammatory secretion by which infection might be carried.

"The number of cases observed by us amounted in all to 45, and they fall into the following groups, of the more important of which we give typical examples. Of the 45 cases observed, 11 (24.4 per cent.) ultimately proved to be cases of scarlet fever, 6 (13.3 per cent.) belonged to the class of doubtful scarlet fever, and 28 (62.2 per cent.) were not scarlet fever. The last class was made up as follows: Tonsillitis, 11 cases; non-specific eruptions, 4 cases; dermatitis, 2 cases; cellulitis, 2 cases; measles (?), 2 cases; röthein (?), 1 case; bronchopneumonia (one complicated with marasmus), 2 cases; gangrenous ulceration of throat, 1 case; general tuberculosis (?), 1 case; and not classed, 2 cases.

"The cases which proved to be scarlet fever may be dismissed with the remark that the certifying practitioner, having seen the case earlier, had probably more definite and specific signs on which to found his diagnosis. We would call attention to a patient in which no desquamation was observed, though the child suffered from well-marked scarlatinal sequelæ, viz., enlarged cervical glands, rheumatic pains in the joints and albuminuria.

"Of the cases of doubtful scarlet fever there was a fairly typical example. A brother admitted at the same time probably had scarlet fever. He also was considered doubtful at first, but was after a time transferred to a scarlet fever ward on acccount of desquamation on the legs. He was dismissed from the latter after five weeks' residence without having contracted scarlet fever.

"As regards cases of tonsillitis no great difficulty is experienced when they occur singly in a family none of the other members of which are suffering from scarlet fever; but when they arise in a family in which one or more of the members are suffering from scarlet fever they are a cause of great anxiety to the physician in attendance. Attacks of this nature are considered by many authorities to be specific and infectious, and yet they do not seem to confer immunity on the person attacked. We have a good example of this in the family the case of one member of which is reported *in extenso*. On the same day a younger brother was admitted. A day or two later an elder brother and a sister were also sent to the hospital. The history in each case was similar, and on admission there was nothing observed but a tonsillitis. The sister and two younger brothers were transferred to the isolation ward on Dec. 7, 1895, and were dismissed well on Jan. 1, 1896, nothing having occurred to warrant the diagnosis of scarlet fever. The third brother was left in scarlet fever ward, and after twenty-six days developed a typical attack of scarlet fever. Similar cases with a like sequel have been observed by ourselves and are doubtless familiar to anyone who has had charge of scarlet fever wards for some time. We have classified such cases under the heading of tonsillitis, though one might be justified in considering them as cases of aborted scarlet fever. The class of non-specific eruption includes, beside the case of which a synopsis is given above, one case of urticaria and two where an erythema of an indefinite character was present, but where neither the history nor the cause of the case led to any reasonable suspicion of scarlet fever.

"Of the unclassified cases, one patient was hysteric and the other was sent in from a public institution along with another child who was suffering fram scarlet fever. She, however, neither had that disease on admission nor did she contract it."
—London *Lancet*, April 3.

Analysis of Two Hundred Gallstone Operations.—Dr. Kehr of Halberstadt, has in six years performed 209 laparotomies for the relief of cholelithiasis. The mortality in this series was seventeen cases, or 8 per cent. Where the stone was in the gall bladder, and was removed either by cystotomy or cystectomy, the mortality was practically 0 per cent. The highest fatality occurred in those cases associated with some grave complication, as carcinoma of the liver or pancreas, etc. The most remarkable results were obtained in the operations on common duct, where there were only two fatal cases in thirty operations, or 6.6 per cent. This is in marked contrast to the results heretofore obtained. Kehr collected eighty two cases from the literature, in which twenty-six died, giving a mortality of 31 per cent. These results should interest physicians, because, while medicine may be said to have not advanced the treatment of gallstones a step in five years, during the same period operative treatment has made great strides in the hands of the surgeon. From 1890 to 1896 Kehr performed his 200 laparotomies on this behalf. These were performed on 174 patients, some having been operated on more than once. Of these, 23 were males and 151 females. Of the latter, 133 were married, 117 of whom had borne children, and 18 were single. The operations are divided into five groups: 1. Those in which the gallstone was situated either in the gall bladder or cystic duct. Under this group there were 127 operations, with only 1 death. The fatal cases occurred in a man, 64 years of age, who had emphysema and arterio-sclerosis. 2. In twenty-one cases a cystectomy was performed, owing to obliteration of the cystic duct or to fibrous contraction of the gall bladder, rendering the latter functionless. The gall bladder was accordingly excised. Only one case died. 3. In thirty cases the stone was situated in the common duct, and was so large that it could not be forced either into the duodenum through the papilla or through the cystic duct back into the gall bladder. In these cases a choledochotomy was performed, the stone being removed through an incision into the common duct. Of this group only two cases terminated fatally. 4. Under this group were included seventeen cases, in which, instead of the suspected gallstone, either some other disease-process (as ulcer of the stomach, echinococcus of the liver, or wandering kidney) was found, or the gall bladder, being free from stones, was, however, adherent to the omentum, stomach, intestine or abdominal wall. Two of these cases died. These cases demonstrated to Kehr, first, that in some instances an exploratory incision is necessary to make a diagnosis; and, secondly, that adhesions between the gall bladder and adjacent structures may produce colicky pain indistinguishable from that produced by a gallstone. 5. The last group included cases in which, in association with gallstones, there existed various complications, as carcinoma of the liver, stomach, common duct, or head of the pancreas, suppurative cholangitis, syphilis of the liver, or liver cirrhosis. This group comprised nineteen cases, ten of which terminated fatally, while nine obtained relief from their symptoms for periods of from one and one-half to ten months.—*Arch. für klinische Chirurgie.*

Variation in the Size of Drops of Even the Same Liquid.—The great variation in size of the drop furnished by different liquids is well understood, but the large divergence in the size of drops yielded by the same fluid, even under ordinary conditions, is not so fully appreciated. Pharmaceutical literature acknowledges the unreliability of the drop as a method of measurement, yet with singular unanimity gives approximating numbers of drops to the fluid dram for similar liquids. This would leave one unfamiliar with the facts to infer that the number of drops to the fluid dram of any given fluid is fairly constant, which is far from being the case, unless much more than usual attention is paid to the proper conditions to secure what might be called the recognized drop of any given liquid. The use of the drop as a means of measurement is on a par with that of the pinch and handful, and all three are quite unsuitable for potent drugs.

The number of drops of water to the fluid dram is usually given by various authorities as about sixty, and similar figures are accorded to such watered preparations as Fowler's solution and dilute hydrocyanic acid. Our attention was first strongly called to the great ease with which the size of drops can be varied under ordinary circumstances, by being consulted by a prominent physician, in regard to the number of fluid drams of dilute hydrocyanic acid to be used in a prescription, where he wished to secure a certain number of drops in each fluid dram of the finished product. Upon inquiring of him the size of the drop desired, it developed that the physician thought that a drop of dilute hydrocyanic acid always represented a minim. In reply to this, forty drops were dropped from the one ounce glass-stoppered bottle holding the dilute acid, into a small narrow-lipped, thin-edged graduate and they were found to measure one fluid dram. The graduate was then elevated and turned until drops began to fall directly from the lip, without the intervention of a guiding-rod, stopper, or any other aid whatever, and one hundred drops were secured from the original forty. In one case the drops were 50 per cent. larger than he expected, and in the other they were only six-tenths of the size anticipated. The larger drops were two and a half times the size of the smaller ones; yet either method of dropping would not be considered unusual.

To show how widely drops of the same liquid will vary in size when obtained under different conditions experiments were made with water, which is much used as a menstruum, and fairly represents several powerful preparations. A fluid dram was dropped under the varying circumstances noted below with a yield in drops as stated:

From the bottom of a ten ounce evaporating dish, the number of drops was 18.

From a two pint funnel, choked with cork for dropping, square, thick end, 24.

From the bottom of a five ounce beaker, 25.

From a six ounce funnel, choked with cork for dropping, square, thick end, 28.

From a large glass stopper, two inches in diameter, 30.

From a five ounce lipped beaker, with guiding-rod, ⅛ inch in diameter, 31.

From a ⅜ inch guiding-rod, taking supply from two ounce dropping funnel, 32.

From a four ounce glass stopped bottle (half full), stopper kept partly in neck, 33.

From a two ounce lipped graduate, offhand, without guiding-rod, 45.

From a one dram lipped graduate, offhand, without guiding-rod, 47.

From a two ounce funnel, choked with cork for dropping, slanting end, 52.

From 3 16 inch diameter guiding-rod, taking the supply from two ounce dropping funnel, 62.

From a 3-16 inch diameter guiding-rod, taking the supply from one dram graduate, 96.

From a ⅛ inch diameter guiding-rod, taking the supply from two ounce dropping funnel, 96.

From a five ounce lipped beaker, offhand, without guiding-rod, 100.

From a five ounce lipped beaker, with guiding-rod, 3 16 inch diameter, 120.

From a pointed guiding-rod, 1-24 inch diameter at point, from two ounce dropping funnel, 160.

From a pointed guiding-rod, 1-40 inch diameter at point, from two ounce dropping funnel, 600.

The drops which were obtained with the very small guiding-rods and from the bottoms of the vessels were abnormal and are only given to illustrate what is possible under certain conditions. The list, however, shows quite plainly how easy it is to obtain drops of water under ordinary circumstances, varying from 33 to 120 to the fluid dram.

There are several factors which cause the drops of the same liquid to vary in size, among which are the adhesion of the fluid mass to the solid which it bathes, the cohesion of the molecules of the liquid to each other, the gravity of the fluid, the temperature, the rapidity of dropping, and the area and shape from which the drop falls. The adhesion of a liquid is greater for some kinds of solids than for others. If a liquid does not wet a substance, it is because its adhesion for such a material is overcome by the cohesion of the liquid. Films of grease covering a dropping surface, in part or completely, have a decided influence in altering the size of the drop. A fluid dropping from such a non-wetted surface has principally the adhesion to overcome, as it is weaker than the cohesion which holds the liquid particles together. When the solid is wetted, cohesion is stronger than adhesion and it is the cohesion which has to be overcome before the drop can fall.

The gravity of any mobile body determines in a considerable degree, its ability to cling to different surfaces and results from certain surfaces for one liquid are not necessarily proportionately correspondent for a fluid of different gravity.

Differences of temperature cause variations in the viscosity of fluids and in this way influence the size of the drop. In liquids which readily become viscid, at not unusual degrees of cold, this factor is most marked. In liquids like water, whose mobility is but little effected by ordinary changes of temperature, the size of the drop shows but slight variation from this cause. As an illustration, water from a two ounce dropping funnel gave 44 drops to the fluid dram at 0° C., 47 drops to the fluid dram at 22°C., and 47 drops to the fluid dram at 100° C. These indentical results were obtained in each of three trials at the three different temperatures.

Rapid dropping furnishes smaller drops than when the dropping is done slowly. This is due to the momentum of the liquid, which as the velocity of its flow is increased, enables it to more readily overcome causes which tend to produce a larger drops.

The area and shape of the surface from which the liquid drops, probably causes the most important differences in the size of drops from any one liquid. The larger the surface to which the fluid can cling and from which the drop mass can secure material at the period of its segregation, the greater the drop will be. Small guiding rods give smaller drops than larger ones, and guiding-rods of similar size with conical ends yield smaller drops than those whose ends are globular. Rounded or globular surfaces are well adapted to illustrate the great influence which is exercised upon the size of drops by the area of the surface from which the drop actually falls. Plane surfaces are not suitable, as it is almost impossible to prevent the dropping from occurring at the edges. In the case of water, above illustrated, the size of the drop steadily increased from the rounded surface 1-40 inch in diameter up to the one ten inches in diameter. At certain diameters for different liquids, a point is no doubt reached, where, from conditions being carried to extremes, a drop is obtained of equal size to that which is possible from the under side of a perfectly level plane surface of unlimited extent.

Where wild guessing is not permissible, fluids should not be dropped, but should be measured. The minim or 1-10 c.c. should be used for describing small quantities of liquids, and in cases where it is absolutely necessary to use drops, but little dependence should be put in their estimated sizes, but an actual trial should be made of the material in the way it is intended to be dropped, that one may know what part of a fluid dram this particular kind of a drop actually represents.—GEO. F. PAYNE, M.D., in *Druggists' Circular.*

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:

Per Annum, in Advance	$5.00
Single Copies	10 Cents.

Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 61 Market Street (Occidental Buildings), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, Venetian Building, Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the *Editor*, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

INFORMATION WANTED.

It would greatly facilitate the prompt delivery of the JOURNAL to those members of the ASSOCIATION living in large cities, if they would kindly furnish this office with their street address in those cases where it is omitted from the wrapper of their JOURNAL, as we have been notified by the postmasters of the larger cities that second-class mail matter not having street address, would be placed in the general delivery to await call.

SATURDAY, JULY 17, 1897.

MEMBERSHIP IN THE ASSOCIATION.

That the ASSOCIATION is growing in membership at an unprecedented rate is perhaps not known to all the members. We therefore take great pleasure in informing them that 763 names were added to the membership list at the Philadelphia meeting.

The books show an increase from June 1, 1896, to July 1, 1897, of 1,500 names. For the same period, our books show an increase of an even 500 on the subscription list.

These are gratifying evidences not only of the sincere desire of the medical profession to organize under the ASSOCIATION banner, but that its JOURNAL is fairly satisfactory. It will be the aim of the present management to make the JOURNAL more and more useful to our colleagues with each succeeding issue.

This is an appropriate occasion to invite members to do their part toward increasing the membership. Help us pass the ten thousand mark before the close of this year. Every one can help. Blank applications for membership can always be had by writing to this office for them. "Be not weary in well doing."

THE ROLE OF THE SPLEEN IN INFECTIOUS DISEASES.

Other than that the spleen plays some part in the destruction of old blood-corpuscles and the generation of new, little is known concerning the function of this organ. That it is somehow affected in the course of many of the infectious diseases is apparently shown by the frequency with which it undergoes enlargement of size in conjunction therewith. Various hypotheses have been propounded as to the nature and the purpose of the alterations that take place, but none has thus far withstood the tests of experimental inquiry. It is therefore a source of satisfaction to note that the subject has recently been taken up and given consideration on a generous scale by BLUMREICH and JACOBY (*Berliner klinische Wochenschrift*, May 24, 1897, p. 444) at the Second Medical Clinic of the University of Berlin. These observers made a careful and scientific study of the influence exerted upon the susceptibility of guinea pigs to infection by bacteria and their toxins respectively by reason of the presence or absence of the spleen. After a little skill had been acquired in the technic of the extirpation the animals operated on speedily recovered and gained in weight.

Diphtheria bacilli and active diphtheria toxin were first experimented with. Twenty-four animals were taken and the spleens removed from twelve. Of each group six animals were now inoculated with the bacilli and six with the toxin. Those of each kind treated with the toxin presented like symptoms, all dying at about the same period; while of those inoculated with the bacteria the six from which the spleens had been removed resisted fatal doses longer than the control animals, the latter dying on an average after 34½ hours, the former after 47 hours.

Fourteen normal animals and twelve from which the spleens had been removed and all inoculated with virulent anthrax bacilli died at about the same time; only one animal deprived of its spleen recovered. These observations with regard to anthrax bacilli are practically in accord with those of others, apparent variations being due to differences in degree rather than in kind. Between animals with and those without spleens treated with pyocyaneus toxin there was little or no difference, although of fifteen from which the spleens had been removed two died (one through an accident) and thirteen recovered, while of twelve normal animals treated similarly eight died and a ninth was made very sick.

Again of eighteen animals without spleens treated with cholera bacilli four died and fourteen survived, while of fifteen normal animals similarly treated thirteen died and two were made very sick.

It would thus appear that guinea pigs deprived of their spleens possess an increased resistance to infection by the bacilli of diphtheria, pyocyaneus and cholera, but not to their toxins. To determine if this peculiarity is dependent upon the removal of the spleen from the body or merely from the circulation the spleen was ligated in nineteen animals. The operation was borne badly, fifteen animals dying in a short while and only four being available for further experiment. In these the results were found to be just the same as when the spleen had been removed from the body. The conclusion would thus seem justified that it is really the removal of the spleen from the circulation that is responsible for the increased resistance of guinea pigs to bacterial infection.

To determine if the blood of animals deprived of their spleens is endowed with the property of diminishing the virulence of bacteria in greater degree than the blood of normal animals virulent cultures of the bacillus pyocyaneus were brought in contact for several hours with defribinated blood obtained from normal animals, as well as from others deprived of their spleens, and the mixtures injected into other animals. The results were constant that the animals treated with mixtures of bacteria and the blood of normal animals died earlier than those treated with mixtures of the bacilli and the blood of animals deprived of their spleens. The conclusion seems therefore justified that the blood of animals deprived of their spleens possesses a greater bactericidal activity than that of normal animals. Bacterial toxins on the other hand behaved in the same way with the blood of both sets of animals; that is their activity was in no wise enfeebled.

In order to determine if experimental infection could be neutralized by hyperleukocytosis and if this result were to be attributed to the bactericidal action of such blood from the presence of the increased number of colorless corpuscles, the blood of sixteen animals was taken and counted before and at various times after extirpation of the spleen. In fourteen considerable increase in the number of leukocytes followed; in two there was a diminution, but in one of these suppuration took place and in the other death resulted on the fifth day from pneumonia. To demonstrate that the hyperleukocytosis was not dependent upon the operation rather than upon the removal of the spleen it was shown that the blood-state did not occur when the remainder of the operation was performed while the spleen was left intact. It was further found also that the hyperleukocytosis resulted when the spleen was merely ligated and thus excluded from the circulation only.

The evidence would thus go to show that *removal of the spleen is followed by* hyperleukocytosis, increased bactericidial activity of the blood and increased resistance of the body to certain forms of bacterial infection. There is thus afforded an explanation why animals deprived of their spleens are more resistant to bacterial infection than to intoxication with bacterial products and also why in diphtheria, in which the toxic factor preponderates, destruction of the bacteria is of so little direct importance, and why the infection of cholera is so readily overcome. It must, however, be remembered that the protective influence of the leukocytes is limited both in degree and in time. Perhaps in this fact is to be found the explanation of the aberrant results obtained with anthrax bacilli.

Now it may be suggested that if immunity to infection on the part of animals deprived of their spleens is due to hyperleukocytosis, opposite results should be secured if bacterial inoculation preceded removal of the spleen. The correctness of such an assumption was demonstrated by inoculating fourteen animals with bacilli pyocyanei and several hours later removing the spleens from eight. Of the latter six died, while of the six control-animals only two died. It may be, that other changes, chemic or morphologic, in addition to hyperleukocytosis, may have some share in the effects produced. Future investigation will have to determine whether the changes effected follow only removal of the spleen or other lymphoid structures or may develop in the sequence of removal of any other important organ. It has already been shown that injections of extracts of spleen, thymus and bone-marrow (lymphoid organs) induce hyperleukocytosis, while extracts of other organs do not. It yet remains for the clinician to determine whether in diseases attended with enlargement of the spleen and hyperleukocytosis, or hypoleukocytosis, these respective conditions bear a constant definite relation to one another and whether the enlargement of the spleen, like the number of leukocytes, is of favorable or unfavorable prognostic significance.

THE NERVOUS ACCIDENTS OF BICYCLING.

The bicycle has become so an important element in modern life that it is certainly worthy of an occasional mention by the medical press. The subject has not been exhausted in its hygienic and medical relations and new points arise from time to time for consideration. A few weeks ago the nervous disorders induced by bicycling were discussed, not exhaustively it is true, by certain English physicians and it was pointed out that excess in this as in other reasonably good things had its more or less damaging influences. Other than medical writers have discussed also the iniquities of this modern indulgence, the bicycle hump and the bicycle face are matters of common jest, not on the principle of ridiculing a false alarm, but as an evidence of the popular taste for the ridiculous even in self-inflicted misfortunes. Still the bicycle becomes daily more popular and its influence on our civilization will be seriously discussed by future historians and students as much as will its physical effects by physicians.

Much of what has been said against the bicycle, without doubt, falls into that class of hygienic criticism that, if sufficiently influential and accepted, would make life miserable by depriving it of all its pleasure. Still there is something to be said to its disadvantage now and then and this is accentuated by the almost universal use of the wheel by persons of all ages and classes at the present time. Extreme youth and advanced age have each their special drawbacks; in the one there is the possibility of overtaxing and possibly of deforming an only partially developed organism, and in the other the general danger of overstrain of an enfeebled one together with the special hazard of aggravating certain senile weaknesses. For the great mass of mankind of either sex the dangers could hardly be said to counterbalance the advantages if it were not for the tendencies to the excessive use and the abuse of what ought to be a pleasant and profitable exercise. The pleasure of rapid movement and the emulation and competition, the sporting instinct that exists in almost every one, all have their part, and the results are often disastrous. To say nothing of the frequent surgical accidents, the bad effects of vesical and prostatic irritation, the heart strain, and other disadvantages that have been frequently pointed out and are incontestable, there are yet other possibilities of evil. Drs. SEMPLE and TAYLOR have reported myelitis as a direct consequence of excessive use of the wheel, and another English physician, speaking from personal experience as an observer of road races and other bicycling sporting events, gives quite a formidable list of the nervous accidents he has seen follow in the participators. Most of them it may be presumed were only temporary, but some may not have been, and temporary or not, none of them were desirable symptoms. It would be interesting to know the extent of the nervous symptoms that actually do occur in scorchers and bicycle racers; as yet we have only a few observations on record, but these are suggestive and lead us to suspect that there are many yet to be reported. The use of the bicycle is rapidly extending and it is only a few years since it became so general; any remote nervous effects of its misuse have therefore hardly had time to develop. With its extended use there have been some improvements in a hygienic point of view; the pneumatic tire, reducing the jar, is one; the improved saddles are another; but modern high gearing and the tendency to sacrifice everything to lightness and speed are perhaps advances in another direction. In any event it will be long before all the medical aspects of the subject are fully discussed; they are all the while developing. But there is certainly room at the present time for a complete investigation of the effects of the altogether too common misuse in many ways of the bicycle upon the nerves and central nervous system.

THE BACTERIOLOGY OF MUMPS.

It does not seem unreasonable to believe that the entire group of so-called self-limited diseases, including among others the exanthemata, pneumonia, acute rheumatism and chorea are dependent upon bacterial invasion. The dependence of many of these upon specific bacteria has already been demonstrated and it is not improbable that the near future will bring similar demonstration for the remainder. The list of the former is steadily growing, while that of the latter is correspondingly diminishing. Among the latest of the disorders which have been shown definitely to owe their origin to microörganismal activity is mumps.

PASTEUR noted in the blood of patients suffering from this disease bacilli 1 μ thick and 2 μ long. CAPITAN and CHARRIN, and also OLLIVIER, observed in the blood and in the urine of such patients small rods in addition to cocci. BOINET found in the blood cocci arranged in part in pairs and in part in chains. LAVERAN and CATRIN, and later MECRAY and WALSH, found partly in exudates and partly in the blood diplococci capable of cultivation on artificial media. At a recent meeting of the Berlin Society for Internal Medicine MICHAELIS (*Deutsche medicinische Wochenschrift*, May 13, 1897, Suppl. 1, p. 93) detailed the results of a number of bacteriologic examinations made by himself and BEIN in cases of mumps observed at the clinic of Professor LEYDEN, who had some time before noticed peculiar diplococci in the sputum of a child suffering from this disease. These bacteria lay principally within pus cells. In all of seven cases of epidemic mumps recently studied the same organism was found both on microscopic examination and on culture, and not only in the secretion of the parotid gland as obtained from STENON's duct, but in two cases also in pure culture in the pus from an abscess and in one of two cases examined in blood obtained by venesection.

In spite of this small number of observations the belief is expressed that in view of the constancy of the results the conclusion is justified that the microorganism found may be considered to bear etiologic relations to the disease. The individual microörganisms are 1 μ in size and resemble the biscuit-shaped meningococci and gonococci, although smaller than these. They lie frequently within the cells, sometimes to the number of eight or ten or more, and are also partly distributed throughout the pus or in long chains or strings. They stain readily with the usual anilin dyes, especially with LOEFFLER's methylene-blue, and they can be decolorized by the method of GRAM. They grow upon the usual culture media, though slowly. Upon agar they develop tiny transparent, dewdrop-like points that do not coalesce. Upon peptone-bouillon they form a white, rather granular than flocculent, deposit, the bouillon itself remaining clear. The growth is more rapid on strongly alkalin than on feebly alkalin media. The bacteria grow also upon ascites-fluid and upon milk, the latter coagulating in the course of forty-eight hours. They are capable of slight movement. Inoculation experiments were unsuccessful, except in the case of a white mouse which died after thirty-six hours. Inocula-

ican Medical Association, as able, honest and honorable as himself, and whose only fault is that they have aborted typhoid fever and for the benefit of humanity have said so and have reported their cases.

It is not necessary, perhaps hardly proper, to call attention to the fallacies in the Doctor's paper, yet one can not help mentioning a few of them, *e. g.*, "The diet should be liquid. . . Milk is the best of all foods." Milk is a liquid outside of the body, but is it a liquid food in the stomach? "When the case has terminated the room should be thoroughly disinfected for at least two weeks before it is occupied and the furniture washed with a solution of bichlorid 1 to 1000." This is fairly good advice for two or three decades back, but insufficient and laborious. We live in an enlightened age now; we simply close up the room and send a stream of formaldehyde gas through the key hole and the next night use the room with safety as a surgical ward. "Such preparations as phenacetin, etc., may be used in small doses, but I deprecate most decidedly the use of the coal-tar derivatives at any stage of the disease." Does Dr. Upshur not know that phenacetin is one of the coal-tar derivatives? "Numerous drugs have been used with the object of abridging typhoid fever, but all clinical experience shows the effort to have been fruitless." "We have no evidence of proof given, except the bold assertions of success by himself and others, and the *testimonials are not worth any more than the testimonials given by hundreds to the so-called cancer cures and kidney cures et id omne genus.*" In one sentence Dr. Upshur shows his respect for clinical experience, coupling it, however, with a gross misrepresentation. In the other he designates the reports of cases of those who have succeeded with the abortive treatment and the opinions they have expressed regarding it—the highest expression of clinical experience—as testimonials and attaches the same value to those of the deluded victims of quacksalvers as to the clinical reports of educated physicians; and because these physicians cure so large a percentage of their cases and in so short a time that Dr. Upshur regards their results as marvelous, he condemns them as impossible and raises the hackneyed question of "errors of diagnosis." In comparing the clinical reports on the abortive treatment of typhoid fever to the "testimonials," generally of impecunious patients given to shameless quacks or patent medicine venders, is a gross insult to hundreds of the ablest and most honorable physicians in all parts of the United States and through them to the entire medical profession, and scarcely less insulting is his theory that all of the wonderful results of the method which he condemns are due to errors "of diagnosis." To accept this theory it would be necessary to believe that physicians who have been at the head of some of the largest hospitals in the United States—that hundreds of physicians who have won high repute and large practice, and many of them high official positions such as high rank on the Medical Staffs of the United States Army in Marine Hospital Service, etc., and have reported 7,857 cases of typhoid fever treated by the method I have advised, are incapable of making a correct diagnosis in one of the commonest and in its typical form, one of the easiest diseases to diagnosticate which they encounter; to believe that the physicians who adopt this method of managing the disease frequently in the midst of epidemics suddenly cease to meet with it; to believe that the hospitals in which the treatment is used acquire a like immunity, and that while in the same locality and during the same epidemics, physicians were treating typhoid with the ordinary death rate and duration of illness—these hospitals were receiving and these physicians were treating these 7,857 cases of a disease which was being mistaken for and presenting pathognomonic symptoms of typhoid fever with a death rate of 1.90 per cent. and an average duration of illness of 12.7 days of those that recovered; that the patient whose temperature dropped rapidly to 99 degrees and afterward died of intussusception, the necroscopy revealing extensive ulceration of Peyer's glands, was an "error of diagnosis;" the patient in whom the treatment was instituted and the temperature dropped from 104.8 to 99.7 on the fourth day and to normal on the tenth, the pulse in the meantime dropping from 96 to 76, the treatment having been previously discontinued, a relapse and death followed and the necropsy showed ulceration of Peyer's glands and intestinal perforation—an "error of diagnosis;" Diazo reaction positive—Widal's test of reaction of serum on Eberth's bacilli characteristic of typhoid fever—disease aborted—"errors of diagnosis." Is Dr. Upshur himself credulous enough to believe all these absurdities?

Aside from the small doses of phenacetin, the use of which is always reprehensible, the recommendations in this remarkable paper are in consonance with the procedures in vogue during most of the passing century; indeed the one remedy from the use of which the Doctor says he has seen marvelous benefit, was recommended and used during the last century in "typhus mitior"—not necessarily a condemnation. It is fair, therefore, to presume that his death rate (a subject upon which he is discreetly silent) is the ordinary 15 to 20 per cent., and his average duration of illness from four to six weeks. He is then to be commended for his unwillingness to "subject his patients to such experimentation" (as the Woodbridge treatment)!

Finally, Dr. Upshur is to be congratulated on his desire for "convincing proof of the brilliant results claimed," a wish which I promise to gratify if he will come to me, and I pledge myself that he shall be able "to approach the treatment of *his* cases of typhoid fever with the assurance of its harmless nature and certainty of cure." I am, my dear editor,

Your most obedient servant,

John Eliot Woodbridge, M.D.

"Life Insurance Fees for Medical Touts."

Hartford, Conn., July 8, 1897.

To the Editor:—Your edition of July 3 contains an editorial entitled "Life Insurance Fees for Medical Touts," which is in its initial statements so obviously unfair to the great majority of life insurance companies, as well as to the medical profession at large, that I beg leave to offer a remonstrance. You begin by saying, "for at least a half a century the American medical profession has been conscious of the great injustice done in the matter of fees for life insurance examinations." Now, I have been a practicing physician and life insurance medical examiner for thirty-one years, and for nearly half that time also the medical director of a large life insurance company. As the examiner of several companies I received, during the early part of my career, $3, and for the latter years $5, for each examination made, and when microscopic examination was called for I was paid from $3 to $5 additional. During all this time I have near heard any objection made by physicians, nor have I felt myself that these fees were unjust. In the days before uranalysis was so universally required, $3 was regarded as good compensation for the twenty-minute or half-hour examination made. Some years later a fee of $5 was allowed in cities and when chemic uranalysis became a general requirement the fee was advanced to $5 in most instances, both in the city and country alike, with an addition for using the microscope. The company with which I am connected (the Connecticut Mutual Life Insurance Company of Hartford) has several thousand examiners, and I do not recall a single instance in which there has been an expression of dissatisfaction with the fees we pay; nor could such a claim be put forward with any degree of fairness. The time and professional ability requisite for this work is as well paid for as in any other branch of medical service. Still more conclusive evidence is found in the fact that fee tables adopted by our medical societies in no instance, so far as my knowledge goes, calls for or suggests even a fee in excess of the amounts named above. Surely this would appear to be a strange way of manifesting to the world a life-long consciousness of great injustice.

Again, you say, "of late this feeling has been intensified by the wanton reduction of fees to medical examiners, while at the same time the salaries of presidents were increased by thousands." It is true, I believe, that one or two companies have reduced somewhat their fees, or made a graded scale of fees, within the past year or two, but no such action has been taken by the great majority of companies. Of course I am speaking of the old line life insurance companies and do not refer to assessment or society insurance at all. The Connecticut Mutual Life Insurance Company and the great majority of similar companies still pay a $5 fee, which has been and is accepted by our examiners as adequate and just. There can be no question, however, that an abundant corps of competent medical examiners can be found in all parts of the United States who are not only willing but anxious to make life insurance examinations for the old fee of $3, including chemic analysis of the urine, and our industrial companies inform me that they find little difficulty in securing competent service at a much lower cost to them. This illustrates the willingness of a large part of the practitioners in this country to perform such service for a fee much less than that generally paid by life insurance companies.

Continuing, you say, "while life insurance companies do not appreciate physicians highly in their proper functions as medical men, etc." Once more I must take exception to your statement. Nowhere is the service of a skilful and conscientious physician valued more highly than in an insurance office. The whole institution of life insurance rests upon the medical estimate of the individual applicant. The amount of money annually expended by life companies to secure competent examiners and to weed out those who are unreliable is very large, and is made necessary by the recognition on the company's part that the very best medical advice must be secured if a safe and stable business is to be transacted. In view of the great number of applicants for the position of examiner, and the high appreciation by the company of what is requisite in an examiner, any physician is surely to consider himself complimented when he is requested to occupy the position.

Criticise, if you please, business methods like those you mention in your editorial, but do not make it appear that the profession is being imposed upon or that life insurance companies are unmindful of the high service performed by their examiners, for this is surely unfair to both parties alike.

Regarding the employment of physicians as agents I care to say nothing beyond this: Should it come to our knowledge that one of our medical examiners was receiving fees from any of our agents for services as solicitor, I should consider the cancellation of his certificate as medical examiner an imperative duty. Very respectfully yours.

GEORGE R. SHEPHERD, M.D., Medical Director.

Color and Finish of Paper for Bookmaking.

SAN JOSE, CAL., July 8, 1897.

To the Editor:—Since I penned a few thoughts in the April 24 issue of the JOURNAL, on the subject of glossy paper for periodical and bookmaking purposes, I have been thinking more on the subject, and the more I think the more I am convinced that the matter needs thorough agitation all round. If one will call to mind the large number of periodicals and books now printed on paper of high glossy finish he will conclude that this style of paper is becoming a "fad."

A journal published in St. Louis entitled *The American Medical Journalist*, notices my former article and makes the following comments: "Dr. Simonton of San José, Cal., objects to the high finish of the paper upon which the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION is being printed, and claims that the 'gloss,' as he terms it, is injurious to the eye, and suggests that the paper should have a dead white finish. The paper used upon the JOURNAL is what is known as an S. and S.C. (Sized and Super-Calendered) book, and is the best quality for periodicals of that character, giving life to the letter-press and affording an opportunity to use half-tone engravings without inserting special sheets for the purpose. If the quality of the paper is reduced, it would be at the expense of the appearance, and illustrations would necessarily have to be printed on separate sheets."

Well may the publishers of the *American Medical Journalist* come to the rescue in defence of glossy paper for periodicals, since the paper on which that particular journal is printed is of such smooth finish that a fly should not venture to light upon it without its life was insured. The paper of this journal is certainly "calendered" in the highest degree of the art.

The editor says that this highly calendered paper "gives life to the letter-press and affords an opportunity to use half-tone engravings without inserting special sheets." I submit that the issue of his journal (June, 1897) in which the words of the last quotation are printed, presents positive evidence that such high finished paper does not receive the ink readily and uniformly from the type. On the contrary, the letter-press is bad.

It stands to reason that paper of highly glossy finish can not take the impression from the type so readily and perfectly as paper of a softer finish.

And it is the half-toned engraving that is leading to this highly calendered paper "fad"; is it?

Must human eyes be sacrificed in order that it may be convenient for the printer to insert half-tone engravings on any page of periodical or book? Give us "quarter-tone" engravings or none at all, rather than to put unnecessary demands on human vision, in this high civilization, which is trying to the utmost the useful organs of sight.

Should the printers of periodicals and books consult their own convenience rather than the convenience, comfort and welfare of those who use and furnish market for their product?

Take up one of these "highly polished" journals and hold it before even a diffused light from a window, so that the rays of reflection reach the eye and it will be found almost if not quite impossible to read the print. Before the direct light of a lamp the difficulty is increased. And at any angle the light reaching the eye from the glossy surface is much greater than from one that is dead white.

For comparison take up the *Forum*, which is printed on paper of proper texture and color. Place this magazine in same positions as you have the "polished" journal and observe the difference and comfort to the eye.

I observe that the imprint of letters on the pages of the *Forum* is perfect, being a positive refutation of the statement that paper of high gloss gives the best letter-press.

A very large number of periodicals and books are now being printed on highly calendered paper and I suppose for the reasons that engravings make a better impression on same, but for reasons which I have set forth the practice should be condemned on all occasions.

All periodicals and books should be printed on a dead surfaced, slightly cream-tinted paper.

A. C. SIMONTON, M.D.

Sterilization of Catgut.

PHILADELPHIA, PA., July 5, 1897.

To the Editor:—Some time about the first of this year an article was published on the sterilization of catgut by treating it with formalin. I am not sure that it was published in your JOURNAL—will you kindly look it up and let me know if I can secure a copy of the magazine containing it, provided you published it?

[illegible] [illegible], M.D.

Polyclinic Hospital.

ANSWER:—See JOURNAL of Dec. 12, 1896, p. 1219.

Fracture of Skull, Rupture of Meningeal Artery. Ligation of Common Carotid, Recovery.

ATHENS, ILL., July 10, 1897.

To the Editor:—Believing the following case would be of interest to the readers of the JOURNAL, I will report it as briefly as possible:

On Wednesday, April 15, 1897, I was called to see T. J. S., carpenter by occupation, age 28, American, and found him lying on the bed profoundly unconscious, pulse 40, breathing stertorous, right pupil dilated, and obtained the following history: Some four hours previously while engaged in building a barn a piece of timber, oak 2 x 8 inches, 11 feet in length, fell from upper part of barn frame while being placed in position by an assistant and dropped a distance of eight or ten feet, striking S. on the top of the head, felling him to the ground, but did not produce immediate unconsciousness. At time of accident he wore a very thick cap on his head, which probably explained absence of external evidence of injury, as close examination of head failed to reveal anything more than a small discolored spot at the point of injury. After receiving the injury he mounted his horse and rode to his home distant about two miles and gave his wife an intelligent account of the accident and requested that the family physician be called. Unconsciousness developed slowly and at expiration of four hours after injury had become profound. I diagnosed fracture of skull with compression of brain and asked for surgical consultation.

Dr. J. A. Prince of Springfield, Ill., saw the case with me and concurred in the opinion expressed, and operation was decided upon, which was performed a few hours later, the patient not showing the slightest evidence of improvement in any way, having lost control of sphincter muscles and having involuntary passages from bowels and bladder.

Incision was made through soft tissues of the scalp down to the skull at the point of injury, and fracture of right parietal bone near superior border was found extending downward and forward considerable distance but no depression of bone. On removal of section of bone with trephine a very firm blood clot presented in the opening, which was enlarged with bone cutting forceps, and clot removed, after which hemorrhage from the middle meningeal artery was very profuse. Packing the opening with gauze, firm pressure and compression failed to control the bleeding. To accomplish this purpose we decided, after giving other methods a fair trial to ligate the right common carotid artery, which was performed in the usual way, the vessel being tied with a double silk ligature, the result was all that could be desired and the operation was concluded in the usual manner and patient put to bed. In a few hours consciousness returned, the pupillary inequality disappeared and the patient made an uneventful recovery, and at this time, now almost three months after operation, expresses himself as being as well in every way as he ever was in his life; he is going about as usual and expects to resume work at his trade at once.

A. L. BRITTIN, M.D.

An Open Letter.

IOWA CITY, IOWA, July 5, 1897.

To the Medical Profession, Members of the Legislature and Citizens of Iowa:

You are doubtless aware that the Board of Regents of the University of the State of Iowa have appropriated nearly $150,000 for the construction and equipment of an hospital to be an adjunct to the Medical Department of the University.

This hospital has been planned to possess the greatest amount of facility for medical and surgical work possible in the present state of science; and, under proper restrictions, it might become a source of great benefit to the needy and indigent requiring medical or surgical treatment.

But the best information accessible indicates that the use and control of the hospital is to be *restricted* to members of the Faculty of the Medical Department of the State University, and that the practical working of the hospital is to be largely under the control of non-resident members of the faculty.

We are also informed that while it is the intention of those in authority to admit the poor, if funds for their board be guaranteed by friends, or by the county from which they come, the well to-do are to be received and afforded advantages superior to those that can be given by local physicians and surgeons, or by local hospitals or sanitariums, provided they pay their board and reasonable charges to the physician or surgeon in charge.

Thus the State, in behalf of a few individuals connected with the Faculty of the Medical Department of the University, enters into competition with every general practitioner, and every hospital and sanitarium in the State; also offering to furnish a set of operating rooms, and all special appliances, to the members of the staff without expense to them; thereby giving them great advantages in competition with the large body of the medical profession, who have no such extraneous aid.

We call your attention to this matter in the hope that you may aid in obtaining from the legislature such enactments as will secure the enforcement of the following rules; without which, in our belief, the hospital should receive no help from the State or the medical profession:

1. That no patient shall be admitted to the hospital or receive treatment therein who is able to pay, or possesses sufficient means to pay for his or her treatment at home, or in a private institution.
2. That no physician or surgeon, a member of such hospital staff, shall receive any compensation for service in such hospital, or receive any pay or gratuity from any patient admitted to such hospital.

It is our belief that the adoption of such rules would in no way lessen the opportunity for good of a State hospital, and could in no way interfere with the *legitimate* work of the members of its staff.

Respectfully submitted,

ELMER F. CLAPP, M.D., Iowa City, Iowa.
C. M. HOBBY, M.D., Iowa City, Iowa.

A Query.

FORT YATES, N. DAK., July 7, 1897.

To the Editor:—Would you kindly give the formula and method of using Schleich's fluid for anesthesia, and as full particulars as possible of Maragliano's serum, in your next issue?

Yours very faithfully,

JAMES W. BAIRD, M.D.

ANSWER: See THE JOURNAL, Dec. 29, 1894, p. 965, for Dr. Würdemann's article on Schleich's method, and THE JOURNAL, Nov. 21, 1896, p. 1105, for an abstract of an article on Maragliano's serum.

BOOK NOTICES.

Manuali Hoepli. Soccorsi d'Urgenza. Pel DOTTORE CARLO CALLIANO. Milano: Ulrico Hoepli. 1897. (*Aid in Emergencies.*) 4ta edizione.

La Morte Vera e la Morte Apparente. Con Appendice "La Legislatura Mortuaria." Pel DOTTORE FELICE DELL'ACQUA. (Real and Apparent Death, with Appendix, Mortuary Legislation.) Milano: Ulrico Hoepli. 1897.

The first of these two little volumes of the extensive and comprehensive Hoepli series, is a work that has received the approval of the Italian sanitary authorities and has passed through four editions, which facts ought to be an index to its worth. On examination the favorable presumption is confirmed; it is a very complete and thorough manual, covering rather a wider field than some of the other numerous publications on the subject, and seemingly very well suited to be utilized as a text-book for ambulance attendants, nurses and others who have to do with the class of cases of which it treats. Its compass will be better understood if it is stated that it gives the elementary facts of anatomy and physiology, the resources available for the immediate treatment of nearly or quite all accidents, poisoning and sudden ailments, the signs of death and the care of the dead, disinfection and asepsis, invalid diet, etc. It concludes with a very satisfactory index, and a number of plates illustrating anatomy, stoppage of hemorrhage, bandaging, transportation of the sick or wounded, etc. If it were only in English it would have our warmest recommendation to American readers.

The second volume gives apparently a very fair statement of the facts as to recognition of real and apparent death, with the Italian law of 1891 in regard to burial and mortuary dispositions generally.

Life of Thomas Wakley, Founder of the first edition of the *Lancet*, Member of Parliament for Finsbury and Coroner for West Middlesex. By S. SQUIRE SPRIGGE, with two portraits. Pages 509. London, New York and Bombay: Longmans, Green & Co. 1897.

We have here the biography of one of the most interesting members the medical profession has produced in Great Britain during the present century. If we consider his pugnacity we must admire the results which he accomplished by it. If we consider him an uncomfortable person to be in controversy with, we must at the same time admit his energy, his faithfulness in the pursuit of right, his great industry, and withal his ready grasp of the spirit of the times.

Wakley was a born reformer. Reformers although followed by many are usually loved by few, for they must run counter to the prejudices of the times, the sentiments of individuals and the customs of the country.

One marvels how it is possible for one individual to have accomplished so much work and at the same time it must be admitted, that done by Wakley was done well. As the editor of a great newspaper he was incomparable, as Member of Parliament for Finsbury, he was always ready with some interrogatory to embarras the party in power and to advance the liberal cause and interest of his constituents. As coroner for Middlesex his career was marked by ability, industry, patience, courtesy, integrity and uncommon learning. These three occupations he carried on at one and the same time.

The career of Wakley is of great interest to every medical man and we commend the perusal of this biography especially to the young medical student, who views with concern the long and rocky road between himself and the goal of his ambition. As for Wakley himself, notwithstanding his success in the House of Parliament and the reforms which he successfully instituted as coroner for Middlesex his best monument is that wonderful medical newspaper which we welcome under the name of the London *Lancet*.

Medical and Surgical Report of the Presbyterian Hospital in the City of New York. Vol. 2, January 1897. Edited by ANDREW J. McCOSH, M.D., and WALTER JAMES, M.D.

This volume contains besides the list of officers, managers, medical board, house staff, house officers the papers on various subjects by the staff of the hospital.

In medicine we have W. Gilman Thompson, Tilden Brown, W. P. Northrup, J. T. Thornley, Francis Kinnicott, and in surgery we have papers by Charles K. Briddon, Forbes Hauks, E. Elliott, and A. J. McCosh.

The volume opens with a well considered paper on cholelithiasis and surgery of the bile ducts by Dr. Briddon. Four cases are reported with analysis.

Gilman Thompson reports on cold tub bathing for typhoid fever and concludes that the cold tub bathing does not ordinarily shorten the duration of the fever. That it does not prevent an occurrence of at least as many relapses that may take place without it. It does not prevent the occurrence of many of the complicated cases to the disease, most of which however are less severe than those that are often presented without it. It does not in any manner preclude simultaneous use of the internal antiseptic or any other recognized methods of treatment.

It is a rational plan of treatment directed toward the support of the nervous system by the double stimulus and as such it is practically useful in preventing those symptoms which result from the overwhelming of the nervous system by the toxin of the disease.

When patients come under the tubbing treatment within the first week of illness it offers the almost certain prospect of the disease running a mild course and it reduces a mortality of many of the severer cases by approximately one-half. These conclusions were based on the study of 284 cases received in six years of treatment, with the total mortality under all forms of treatment of 14.79 per cent.

The paper on renal tuberculosis by Tilden Brown is a careful study.

Transactions of the Southern Surgical and Gynecological Association. Vol. IX. Ninth session, held at Nashville, Tenn., Nov. 10, 11 and 12, 1895. Published by the Association. 1897.

This session was held under the presidency of Dr. E. S. Lewis, and was marked by harmony in its methods and enthusiasm in the professional work before it. Forty members were present.

The volume presents the same handsome appearance as its predecessors and it is on the same high plane. It contains the minutes of the session and all the papers read, with the discussions thereon.

The next meeting of the Association will be held in St. Louis, under the presidency of Dr. George Ben. Johnson of Richmond.

NEW INSTRUMENTS.

A SET OF NEW CURETTES FOR OPERATING IN THE NASO-PHARYNGEAL VAULT.

BY HENRY W. WANDLESS, M.D.
CONSULTING OCULIST AND AURIST, PARKLAND CITY HOSPITAL; CHIEF SURGEON DALLAS CHARITABLE EYE, EAR, NOSE AND THROAT INFIRMARY.
DALLAS, TEXAS.

The cuts given herewith represent a set of curettes which I have devised for operating in the vault of the pharynx. They are specially designed for the removal of adenoids from the vault, granulations, and for curetting the mucous membrane in order to stimulate it to healthy functional activity. These curettes are made in pairs of which there are two. Each pair is composed of two sizes for large and small vaults and is designed for special conditions and localities which are described with each. It has been found that these curettes meet practically all the requirements in operating upon adenoids within the vault, except tumors that are too large to pass within the ring of the curette. Fig. 1 represents the first pair, which is adapted to the posterior walls of the vault only. It does not reach the roof of the vault, because the blade is not set on an angle for the roof. It is intended for this curette to have as near the same curve of the vault as possible, and when it sweeps over the walls it always conforms to the shape of the vault. When introduced the tumors pass within the ring of the curette and are cut off as the curette is made to sweep over the posterior walls. When the tumors have become hard as they often do, especially from age, considerable force is necessary to sever them from their attachment; and in such cases this is the only instrument with which I have had satisfactory success. This curette is not adapted for the removal of tumors in the roof of the vault, because it is impossible to get a curette to conform to the curves of both the roof and the posterior walls. For that purpose I have designed a second pair shown in Fig. 2. This curette may be used for general use, and all adenoids may be removed with it except those that have become hard. It will be observed that the cutting edge of this instrument is set at an angle of about 45 degrees from the handle and when introduced its edge strikes the mucous membrane on its posterior walls at about the same angle; but if the curette is pushed far up and the ring brought well forward against the post-nasal septum at the same time lowering the handle, the blade rests flat against the roof and as the sweep is made over the vault the curette engages the tumors within its rings and brings them away.

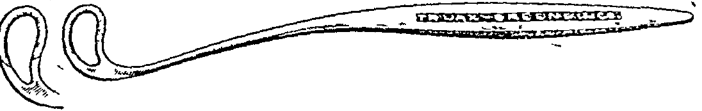


Figure 1.

Any instrument which is not so adapted fails in its purpose to remove the tumors from the roof and simply scrapes those from the posterior walls. It is well to add here that the tumors in the roof around the post-nasal nares do considerably more damage than those on the posterior walls, and it is therefore much more important to remove them. Tumors within the posterior nares can not be reached with these curettes and are best removed with a Bosworth snare. I claim considerable excellence for these curettes, not because they bear my name but because of my practical experience in operating with them, which has been very satisfactory.

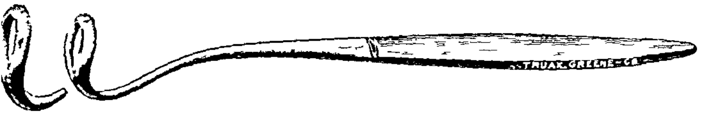

Figure 2.

For removing granulations from the vault and stimulating the mucous membrane, I only use the second pair, Fig 2. The granulations come away readily with moderate force and without much injury to the membrane.

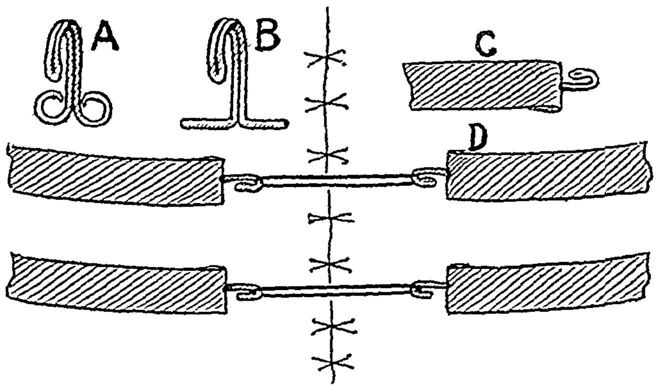
For stimulating the membrane in cases of chronic naso-pharyngeal catarrh I have used this curette with very happy results.

The curettes are made by Chas. Truax, Green & Co., Chicago, Ill.

TENSION ADHESIVE STRAPS.

BY E. H. KING, M.D., MUSCATINE, IOWA.

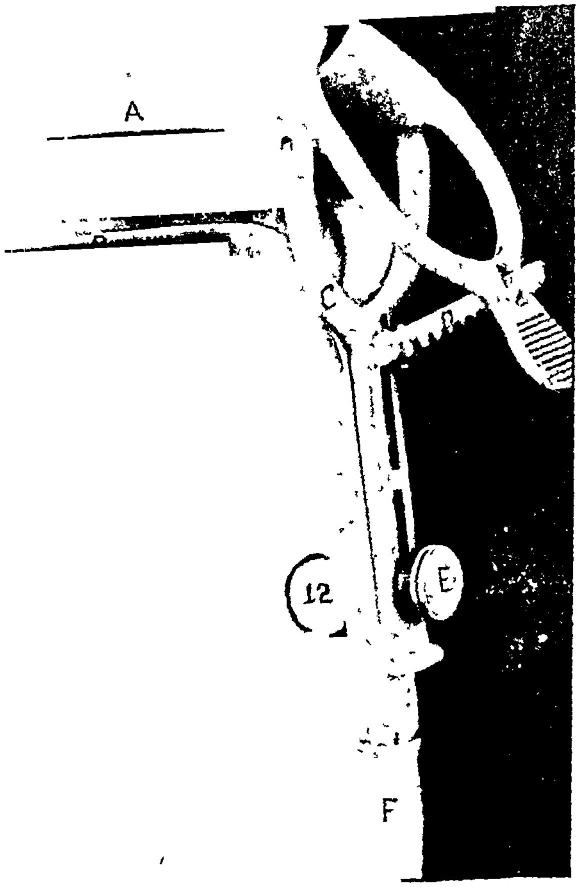
The greatest objection to the use of adhesive straps over wounds arises mainly from a collection of crusts or dried secretion under them, and from the difficulty of inspecting and changing the underlying dressings. This difficulty can be easily remedied by taking common dress hooks, A, bend the circular parts of the shank at a right angle, B, and fix them on the end of an inch strap of Meads, a similar adhesive plaster, C. The straps with the hooked ends may be placed one inch or more from the border of the wound, D, on either side and tension made with small rubber bands over any desired dressing, which will thus be comfortably retained in place. By unhooking the bands, the dressing may be removed without disturbing the straps, wound or patient. These hooks thus made were originated by me. I have used them over twenty years with satisfaction. There is no patent on them and the profession is welcome to the idea.



A VAGINAL SPECULUM.

BY G. R. FOX, M.D., PLAQUEMINE, LA.

I present herewith a photograph of a vaginal speculum which I have recently invented. The instrument is similar to Graves' in the mechanism for the vertical expansion of the blades, but has the following improved features. Instead of the screw used in most similar instruments to keep the distal ends of the blades expanded, I have adopted a ratchet and pawl mechanism, which permits the operator to expose the cervix uteri very quickly, and adjust the instrument with one hand, and to release the blades as quickly when he desires to remove the instrument.



Another improvement is a funnel shaped opening at the rear portion of the lower blade leading into a hollow shank on same, to which a piece of rubber tubing is affixed, thus providing a ready outlet for fluids while using the speculum.

The instrument is aseptible, and the lower blade can be detached and used as a Sims speculum.

Automatic Adjusting Thermometer.—The strain and inconvenience of the ordinary thermometer in severe prostration is avoided by the contrivance of Prof. Cornet, which holds the thermometer automatically in the armpit, by means of a broad spring which passes over the shoulder. The thermometer is curved to fit and can be read without removing.—*Deutsche med. Woch.*, June 3.

ASSOCIATION NEWS.

Competition for the Senn Medal.—Pursuant to a resolution adopted by the Section of Surgery and Anatomy of the AMERICAN MEDICAL ASSOCIATION, June 4, 1897, I have been appointed by the Chairman, Dr. Reginald H. Sayre, as Chairman of the Committee charged with the awarding of the Senn Medal for 1898. The other members of the Committee are Drs. H. O. Walker of Detroit, Mich., and S. H. Weeks of Portland, Me.

1. A gold medal of suitable design is to be conferred upon the member of the AMERICAN MEDICAL ASSOCIATION who shall present the best essay upon some surgical subject.

2. This medal will be known as the Nicholas Senn Prize Medal.

3. The award shall be made under the following conditions: *a.* The name of the author of each competing essay shall be enclosed in a sealed envelope bearing a suitable motto or device, the essay itself bearing the same motto or device. The title of the successful essay and the motto or device to be read at the meeting at which the award is made, and the corresponding envelope to be then and there opened and the name of the successful author announced. *b.* All successful essays become the property of the ASSOCIATION. *c.* The medal shall be conferred and honorable mention made of the two other essays considered worthy of this distinction, at a general meeting of the ASSOCIATION. *d.* The competition is to be confined to those who at the time of entering the competition, as well as at the time of conferring the medal, shall be members of the AMERICAN MEDICAL ASSOCIATION. *e.* The competition for the medal will be closed three months before the next annual meeting of the AMERICAN MEDICAL ASSOCIATION, and no essays will be received after March 1, 1898.

Competitors will address their essays to the undersigned.

J. MCFADDEN GASTON, M.D., Chairman.

1½ Edgewood Ave., Atlanta, Ga.

SOCIETY NEWS.

Twelfth International Medical Congress.—The President and Secretary have issued the following circular under date of June 13 (old style) presidents of important medical societies:

Dear Sir:—His Majesty the Emperor of Russia has given authority to hold at Moscow, on the 19th to the 26th of August, 1897, the Twelfth International Medical Congress, and has deigned to take it under his august protection. Desiring to assure to this great reunion, learned men of the highest character, and that the international character of the meeting shall be marked, the Executive Committee has addressed itself to the most important scientific societies of the world and begs that they will send representatives to the said Congress. The Committee hopes that the honorable society of which you are the president will not refuse to contribute to the *éclat* of the next scientific *fête* of Moscow, by sending delegates, to whom it will be happy to accord the highest consideration. Accept, dear Sir, assurances of the highest consideration.

J. F. KLEIN, President.

S. S. KORSAKOW, for the Secretary General.

The following have had credentials issued for Moscow by the AMERICAN MEDICAL ASSOCIATION:

Drs. L. Ashton, Dallas, Tex.; Frank Billings, Chicago; W.
G. A. Bonwill, Philadelphia; D. R. Brower, Chicago; Augustus
P. Clarke, Cambridge, Mass.; Judson Daland, Philadelphia;
Charles Denison, Denver, Colo.; Henry B. Favill, Chicago;
Thos. H. Fenton, Philadelphia; Geo. Ryerson Fowler, Brook-
lyn, N. Y.; Wm. H. Forwood, U. S. A.: Jacob Frank, Chi-
cago; Henry Gradle, Chicago: Alex. J. Campbell, Syracuse,
N. Y.: J. R. Hildreth, Cambridge, Mass.: Chas. H. Hughes,
St. Louis, Mo.; Florence W. Hunt, Chicago; H. L. E. John-
ston, Washington, D. C.: Wm. D. Kelly, St. Paul, Minn.; J.
O. Knipe, Norristown, Pa.; O. Litzenberger, Converse, Ind.;
T. Mortimer Lloyd, Brooklyn, N.Y.; Thos. McDavitt, St. Paul,
Minn.: Harold N. Moyer, Chicago; J. O. Malsbury, Peru, Ind.;
F. S. Milbury, Brooklyn, N. Y.; Thos. H. Manley, New York;
Abner M. Miller, Bird in Hand, Pa.; John H. Packard, Phila-
delphia, Pa.; Theophilus Parvin, Philadelphia, Pa.; Geo. M.
Preston, Lynchburg, Va.; Nicholas Senn, Chicago; Catherine Slater, Chicago; Edmund H. Stevens, Cambridge, Mass.; Eugene S. Talbot, Chicago; Fred C. Valentine, New York; J. Henry Woods, Brookline, Mass.

The following party sailed from New York, Saturday, July 3, 1897, by the North German Lloyd Express Steamship *Werra*:

Dr. Catherine Slater, Aurora, Ill.; Miss M. Costigan, Chicago, Ill.; Miss Isabel McIsaacs, Chicago, Ill.; Dr. Harriet E. Garrison, Dixon, Ill.; Dr. I. N. Wear, Fargo, N. Dak.; Dr. A. E. Abrams, Hartford, Conn.; Mrs. Abrams, Hartford, Conn.; Mr. D. A. Bishop, Jersey City, N. J.; Mrs. Bishop, Jersey City, N. J.: Miss Bishop, Jersey City, N. J.; Dr. W. H. A. Bonwill, Philadelphia, Pa.; Miss E. Lincoln, Providence, R. I.; Miss Anne L. Gorman, Providence, R. I.; Mrs. Lillian Condell, St. Louis, Mo.; Miss Grace Reynolds, Sugar Hill, Ill.; Dr. B. T. Whitmore, Chicago, Ill.; Dr. Jas. G. Hyndman, Cincinnati, Ohio; Mrs. Hyndman, Cincinnati, Ohio; Dr. F. B. Galbraith, Pontiac, Mich.; Mr. Galbraith, Jr., Pontiac, Mich.; Dr. W. F. Southard, San Francisco, Cal.; Dr. W. F. Forwood, Washington, D. C.; Mr. N. B. Scott, Wheeling, W. Va.; Mrs. Scott, Wheeling, W. Va.; Mr. Jos. Stone Perry, Worcester, Mass.; Mrs. Perry, Worcester, Mass.; Miss Josephine Perry, Worcester, Mass.

The following comprise the Athens and Constantinople section on the same vessel:

Dr. J. H. Woods, Brookline, Mass.; Dr. George Ryerson Fowler, Brooklyn, N. Y.; Mrs. Fowler, Brooklyn, N. Y.; Dr. T. N. Lloyd, Brooklyn, N. Y.; Dr. Daniel R. Brower, Chicago, Ill.; Dr. D. R. Brower, Jr., Chicago, Ill.; Dr. Nicholas Senn, Chicago, Ill.; Dr. W. N. Senn, Chicago, Ill.; Dr. Eugene S. Talbot, Chicago, Ill.; Dr. Lucy Waite, Chicago, Ill.; Dr. Casey A. Wood, Chicago, Ill.; Mrs. Wood, Chicago, Ill.; Dr. Edward K. Root, Hartford, Conn., together with Mrs. Fowler, Brooklyn, N. Y., and Mrs. Wood, Hartford, Conn.

LARYNGOLOGICAL SECTION INTERNATIONAL CONGRESS.

At a special meeting of the Oto-Rhino-Laryngological Society of Moscow, held June 21, 1897, it was decided that a "bureau" should be instituted for the convenience of members of the Twelfth Section of the Twelfth International Medical Congress (Otological and Rhino-Laryngological Section). The object of this bureau will be to give all information needed, not only as to matters concerning the Congress, but as to all other matters where our visitors may require assistance or information. This reference-bureau will be open from 7 to 9 P. M., from the 13th to the 19th day of August, in the Doctors' Club (Bolshay Dmitroffka), and during the meetings in the room of the Section XII b. (Laryngo-Rhinology). I. N. SCOTT, President.

ARRANGEMENTS FOR THE CONGRESS.

Transportation free of charge in first-class carriages from the Russian frontier to Moscow. Half-rate tickets will be issued to members of the Congress by the French, Italian, Spanish, Swedish and Norwegian, and Oriental railways, but not by the German roads. Reductions in fare are offered by many European steamships, but not by the transatlantic companies.

Foreigners must be provided with passports, properly *viséd* by a Russian Consul in the country to which they belong. The passports will be inspected at the frontier. Committees of Russian delegates will be present at the frontier stations to supply information and assistance, and there will also be committees at the Moscow railway stations, as well as offices, where information with regard to lodgings, etc., may be obtained. If physicians take their wives, or other members of their family, they will have to pay full railroad fares for them, but a committee of women, presided over by Mme. Sklifossovsky, will look after the ladies that go to the Congress and see that they have a good time. Rooms can be had at from $1 to $3 a day, with morning and evening coffee, and dinners in good Moscow restaurants cost from 40 cents to $2. A buffet will be opened in the building where the Congress meets, in which meals may be had at very low prices.

Physicians intending to be present must apply to the treasurer, Prof. N. Filatow, Moscow, for tickets of membership, inclosing 10 rubles or $4. The tickets will serve to identify them and will entitle them to take part in all the meetings and excursions and also to all the publications of the Congress. Scientific men, veterinary surgeons, pharmacists and dentists may also obtain tickets, as extraordinary members, but no mere students of medicine can attend in any save their private capacity.

The Congress, which is held under the patronage of the Czar and the Grand Duke Sergius, opens August 19 (August 7 according to the Russian calendar) and closes August 26 (14). Railroad tickets are good from July 1 to October 10, and thirty-five pounds of baggage may be carried free. Several excursions are being arranged for the benefit of members of the Congress, to the monastery of St. Sergius, to Nijni Novgorod, to the Crimea and to the Caucasus. Communications should be sent to the General Secretary, Clinic for Nervous Diseases, Moscow.

American Association of Obstetricians and Gynecologists.—The American Association of Obstetricians and Gynecologists will hold its tenth annual meeting at the Cataract House, Niagara Falls, Tuesday, Wednesday, Thursday and Friday, Aug. 17, 18, 19 and 20, 1897, under the presidency of Dr. James F. W. Ross of Toronto. The railways have granted reduced fares on the certificate plan to all who attend the meeting; the Cataract House has made a reduction from its regular tariff of charges; the place of meeting is a famous one; the season of the year auspicious, and everything seems to conspire to justify a prediction that this will be a large and interesting meeting of this famous Association. The date of the meeting has been fixed in mid-August, apart from college sessions, during the vacation season and at a place where many people like to spend a part of their outing. The climate of Niagara is always desirable during the heated term, the spray from the cataract giving it a healthy moisture and coolness that is at once invigorating and charming. To visit Niagara under the auspices of this Association will afford the tourists exceptional opportunities for the enjoyment of a rare and radiant scenery that is the most sublime in the world. One session will be devoted to the exhibition of specimens and giving their history. The scientific work of the Association will begin on Tuesday morning at 10 o'clock and end Friday at 1 o'clock, and it is expected to so arrange the program as to afford the members opportunity to visit the places of interest each day on the adjournment of the afternoon session. It is expected that the inducements to attend this meeting are such that Fellows will not only come themselves but bring their families and invite their friends as as well to visit the wondrous cataract.

PUBLIC HEALTH.

Medical Inspection of Chicago Schools.—Incited thereto by the publication of the results of the first year's medical inspection of schools—first undertaken in this country by the Boston Board of Health under the supervision of Dr. S. H. Durgin, the able and energetic executive of that board—an appeal was made to the Chicago City Council in the spring of 1896 for an appropriation to defray the expenses of a similar inspection of the public and parochial schools of the city. "Financial stress" dictated the refusal of the appeal; but the Assistant Commissioner, Dr. F. W. Reilly, was so much impressed with Dr. Durgin's showing that eight of the ten medical inspectors of the department were relieved from all other duty at the end of August, 1896, and assigned to this special work for the ensuing school year—Sept. 3, 1896, to June 30, 1897. Dr. Reilly thus sums up the work accomplished with this small force:

> The public and parochial school attendance during the period aggregated upward of 272,000—about 208,000 enrolled in public schools and nearly 65,000 in parochial schools. These occupied 572 separate buildings—234 city public schools, 131 branch and rented public schools and 207 parochial schools. Regular systematic inspections of each school building were obviously out of the question with the force at hand, and the work of the inspectors was therefore based upon physicians' notifications of cases of contagious and infective diseases occurring in their practice. Day by day each medical inspector was notified of the existence and the locality of every such reported case in his district, whereupon he proceeded at once to ascertain if the patient had been in attendance at any school: if not, his duties terminated with seeing that the case was properly isolated and the necessary precautions against spread of the contagion or infection on the premises and in the neighborhood were duly observed. If, on the other hand, the patient had been attending school the school was at once visited and taken charge of by the inspector so far as relates to carrying out and enforcing precautionary measures against further spread of the disease, to the remedy of insanitary conditions on the school premises, etc. In cases of diphtheria and scarlatina the throats of the children in the same room as the patient were examined after the method of Dr. Durgin; the teacher was instructed to watch for certain symptoms and to report their appearance to the inspector, and other appropriate actions were taken and surveillance maintained as long as deemed necessary.
>
> During February, March and April the work was interfered with by various emergencies—for example, in February every available attaché of the department was engaged in looking up, reporting and relieving cases of distress and destitution among the unemployed and in the administration of the Mayor's relief fund. Nevertheless, a total of 1,181 visits were made to the schools during the school year; 4,023 cases of contagious and infective diseases were located and taken charge of for preventive purposes; insanitary conditions in 63 public schools were reported to the Board of Education and similar conditions were remedied in 53 homes of patients.
>
> An important feature of the work was the examination, as to vaccinal status, of the pupils of schools visited. Nine hundred and fourteen such school examinations were made, covering a total of 90,220 scholars, 81,810 in public and 27,410 in parochial schools. Through these examinations 47,310 vaccination or revaccinations were secured, 37,470 of public scholars and 9,840 of parochial scholars.
>
> Of the diseases reported diphtheria was the most prevalent; 744 individual reports of cases among school children, leading to the disclosure of 2,619 cases at homes. There were 231 school cases of scarlet fever and 745 home cases. Forty-six reported cases of measles led to the discovery of an epidemic prevalence of this disease in several sections of the city during November 1896 and again in May and June 1897. In October an epidemic of impetigo contagiosa spread through seven schools of the north division of the city, but was arrested in a few weeks, after excluding 107 cases from the schools and instituting proper preventive measures. Two schools were found afflicted with pediculosis to such an extent as to demand radical treatment. One case of tuberculosis was found at school in such an advanced stage as to justify exclusion from school attendance; this patient died before the close of the school year.
>
> Stomatitis was found so prevalent in many schools that, upon the advice of the Medical Inspectors, the teachers instructed pupils to bring individual drinking cups from their homes and forbade the common practice of putting the lips directly to the water faucets for drinking.
>
> The commonest sanitary defects of school building reported are uncleanliness; dirty floors, passages and stairways; damp and filthy basements; foul water-closets located near furnaces, so that poisoned air is driven through the building, in which cases teachers suffer from headache, "sore throat," etc. Among other insanitary conditions noted are defective plumbing, stagnant pools on adjoining lots, dirty alleys, overflowing garbage boxes and general lack of sanitary policing. In few of the older school buildings is there any provision for drying the feet and clothing in wet or stormy weather. So far as practicable the School Board caused many of these defects to be remedied.

The present Commissioner of Health, Dr. Arthur R. Reynolds is so thoroughly convinced of the value of this work that he purposes making another appeal to the council for an adequate force of inspectors. New York has recently appointed 150 physicians for this service while Boston, with a population of less than half a million, employs 50 with an average of four schools and 1,400 pupils to each.

Smallpox at New Orleans in 1896.—Dr. W. H. Woods, the chief sanitary inspector of that city, has made the following com-

Russian Medical Institutions.—Dr. S. M. Malischew of Rostaw, writes to the *Deutsche Med. Woch.*, No. 14, to correct several inaccurate statements in various articles that have appeared recently on this subject. He explains the official medical service as follows: Russia is divided into 97 governments. Two-thirds of these are governed each by an official appointed by the State, and the other third by a local institution known as the Semstwo, which has charge of the affairs of the government, including the medical and sanitary. The Semstwo of the Moscow government was the first established (1864), and possesses an ideal medico-sanitary organization, from which the rest were modeled. It has a population of a million and a half, and yet the medical service is so arranged that it is within the reach of all, effective and fruitful of results. This is accomplished by dividing the government into 118 medical districts. The physician-in chief of each district resides in the hospital erected in the center of the district, and takes charge of the sick in the country around for a distance of twelve wersts. (One werst = 1,066,781 meters.) The hospital has usually a capacity of twelve to fifteen beds, dispensary, etc., with a pavilion apart for maternity cases and another on the other side for contagious diseases. In ten of the districts there is also a building for chronic patients. All these hospitals and the medical assistance, dressings, etc., are free. Vaccination and sanitary oversight of the schools are also in the hands of the head physician, who has an assistant where needed. The sanitary conditions of the government are in charge of a corps of eight or nine special physicians, some of whom coöperate in recording the medical statistics of the government. The physician receives his residence free, heated and lighted, and also free transportation and 100 to 150 roubles a month. (The rouble = about 55 cents.) The administration of the affairs of the medical department is in the hands of what is called the Health Council, composed of all the district physicians, and five or six members of the Semstwo. This coöperation of medical men and the officials best acquainted with the economic and financial conditions, etc., of the government, results in fruitful action. There is besides all this a vaccine institute, a colony for the insane near Moscow with 1700 acres of land, and a medico-statistic bureau in Moscow. Every two or three years all the physicians in the government meet in a general congress, the transactions of which are published. The expense of all these institutions amounts to almost a million roubles, part of which is contributed by manufacturing firms and landed proprietors. The state is planning to introduce the Semstwo into other governments as soon as possible, but has slightly restricted its independence of action since 1890.

Washington.

Health of the District.—The mortality for the past week was 128, of which 60 were white and 68 colored. The prominent causes of death were, diarrheal diseases 29; brain disorders, 17; lung diseases 19, of which 15 were from consumption. There were 3 fatal cases of diphtheria and 3 from whooping-cough, and 2 from typhoid fever. No new cases of scarlet fever were reported.

The New Superintendent of Charities.—Mr. Herbert W. Lewis has been appointed Superintendent of Charities to succeed Colonel Tracey, deceased.

Medical Society.—At the stated meeting of the Medical Society held on the 5th inst., the semi-annual business of the Society was transacted. The treasurer, Dr. Franzoni, made his report. A number of applications for membership were received. The hot weather had a reducing effect upon the attendance of the Society, only seven out of three hundred and seventy-seven members being present.

To Locate the Isolating Hospitals.—The Commissioners have addressed circular letters to the different hospitals, setting forth the terms upon which they will agree to the location of the isolating wards. Thirty thousand dollars has been appropriated and is now available for that purpose. The diseases which will be treated in these wards are scarlet fever, measles, erysipelas and other contagious diseases of less gravity.

Central Dispensary and Emergency Hospital.—At the July meeting of the Board of Directors of the Hospital, the attending staff made the following report: Number of new cases treated, 1,329; number old cases, 2,540; total number of cases treated, 3,869; number of deaths, 7; number of post-mortems, 4; number of operations, 226; number of ambulance calls, 39.

THE PUBLIC SERVICE.

Army Changes. Official List of changes in the stations and duties of officers serving in the Medical Department, U. S. Army, from July 3 to 9, 1897.

Capt. William F. Lippitt, Jr., Asst. Surgeon (Ft. Leavenworth, Kan.), leave of absence granted to take effect about July 24, 1897, is changed to take effect when his services can be spared by his post commander, and is extended one month.

Capt. Henry P. Birmingham, Asst. Surgeon, on being relieved from duty at Ft. Trumbull, Conn., by Major Woodruff, will proceed to Chicago, Ill., and report for duty as attending surgeon and examiner of recruits, relieving Capt. Norton Strong, Asst. Surgeon. Capt Strong, on being thus relieved, is ordered to Ft. Myer, Va., for duty, relieving Capt. William H. Arthur, Asst. Surgeon.

Major Louis M. Maus, Surgeon, is relieved from temporary duty in the office of the Surgeon-General of the Army, and will on Aug. 2, 1897, report for duty at Ft. Hamilton, N. Y., relieving Major Paul R. Brown, Surgeon. *Major Brown, on being thus relieved, is ordered to Ft.* Keogh, Mont., for duty, relieving Major Ezra Woodruff, Surgeon. Major Woodruff, on being thus relieved, is ordered to Ft. Trumbull, Conn., for duty, relieving Capt. Henry P. Birmingham, Asst. Surgeon.

A board of officers to consist of: Col. William H. Forwood, Asst. Surgeon-General; Major George W. Adair, Surgeon; Major Walter Reed, Surgeon; Major James C. Merrill, Surgeon; Capt. Leonard Wood, Asst. Surgeon, is constituted to meet at the Army Medical Museum Building, Washington, D. C., on Monday, Sept. 27, 1897, at 10 o'clock A.M., *for the examination of candidates for admission to the Medical Corps of the Army.*

CHANGE OF ADDRESS.

Anderton, W. B., from New York to East Quogue, L. I., N. Y.
Bonner, M. H., from Nashville to Murphreesboro, Tenn.
Battell, J. Geo., from Grand and Western Avs. to 790 N. Leavitt St., Chicago.
Clark, J. F., from Angola to 120 W. Lincoln Av., Goshen, Ind.
Cresswell, Willis W., from Minneapolis to Dundas, Minn.
Calawell, W. S., from Edinburgh, *Scotland, to care of Union Bank of* London, London, England.
Ebert, R. G., from *Philadelphia, Pa., to care of Dr. W. H. Saylor*, Hamilton Bldg., Portland, Ore.
Eads, S. O., from Somerset, Ky., to Arthur, Ill.
Fellman, G. H., from Oak Park, Ill., to 289 Pavonia Av., Jersey City, N. J.
Houston, Jas., from New York, N. Y., to Swartz Creek, Mich.
Kolmer, J., from 203 N. Illinois to 19 W. *Ohio* St., Indianapolis, Ind.
Johnson, L. D., from 819 W. Harrison St. to cor. Lake St. and California Av., Chicago.
Linjer, O. E., from Starbuck to St. James, Minn.
Makuen, G. H., from Philadelphia to Cresson Springs, Pa.
Rathbone, F. W., from Albuquerque, N. M., to Tonganoxie, Kan.
Sleicher, J. M., from Chicago, Ill., to 102 Main St., Watertown, N. Y.
Scofield, W. K., from Philadelphia, Pa., to 62 South View Av., Stamford, Conn.
Stone, R. F., from 250 N. Illinois *to* 14 W. *Ohio* St., Indianapolis, Ind.
Stewart, D. D., from 2602 N. 5th to 108 S. 17th St., Philadelphia, Pa.
Ward, Milo B., from Topeka, Kan., to Rialto Bldg., Kansas City, Mo.
Wolff, A. S., from Brownsville to Isabel, Texas.

ORIGINAL ARTICLES.

CHEYNE-STOKES RESPIRATION PHENOMENA.

Presented in the Section on Practice of Medicine, at the Forty-eighth Annual Meeting of the American Medical Association, at Philadelphia, Pa., June 1-4, 1897.

BY N. S. DAVIS, JR., M.D.
CHICAGO, ILL.

Mr. ——, merchant, 73 years old, of good habits and good family history, came under my care in September last. His health had not been robust for many months. In midsummer his legs became edematous and he then first consulted a physician. He was found to have dilatation of the heart, a slight aortic murmur, atheroma to a moderate extent of the peripheral arteries and interstitial nephritis. His symptoms underwent no material change up to September, when I first saw him. As time went on he grew feebler, thinner and mentally depressed. He had little appetite for food or drink. He was often sleepless. About the middle of October he was too feeble to walk, and rarely slept more than an hour at a time. At night he was tormented by hallucinations which were very persistent. At this time Cheyne-Stokes respiration first manifested itself. The rhythmically increasing and diminishing respiratory movements with short pauses were very noticeable. The periods of apnea were short and the periods of dyspnea were not severe. The pulse was quite regular and was kept at about 85 by strophanthus. The pupils showed no change in size and there was no hebetude during apnea.

Cheyne-Stokes respiration was not constant at this time. It lasted for several days, and disappeared only to reappear from time to time for a few hours or days. Occasionally apnea was almost wanting, and even at the height of dyspnea the respiratory movements were not labored.

In November he improved; respiration became normal, sleeplessness was less troublesome and hallucinations were more infrequent and less persistent. Early in December he grew worse, Cheyne-Stokes respiration reappeared in an aggravated form and persisted for almost a month until he died. Dyspnea was more intense than during the first attack of Cheyne-Stokes respiration and the pauses were longer. His pulse quickened during apnea, and as respiratory movements grew shallower his eyes converged slightly, his lids closed and he seemed to be in deep sleep. If at this time his lids were lifted the pupils were uniformly found to be closely contracted. Conversation with him was slow, for he would cease speaking and apparently become unconscious during the period of apnea. With the first few shallow breaths his lids would open and his eyes would roll slightly as they are apt to do when one is suddenly roused from deep sleep. He would, so soon as respiration was fairly established, resume a conversation without interruption of argument or break in the continuity of events that he might be describing. During apnea the power of speech was lost and mentality seemed suspended. If spoken to when thus apparently dozing he was not conscious of the question. Conversation with him was tedious, for these pauses occurred once in every eighty to ninety seconds and lasted about twenty-five seconds. The dyspnea was very wearisome to him. He was never cyanotic.

I have described this case as it illustrates Cheyne-Stokes respiration in its mildest form, and in that form in which all the accompanying rhythmic phenomena of pulse, eye and mind are present. In 1818, Cheyne (Dublin Hosp. Rep., 1818, vol. ii) first called attention to rhythmically ascending and descending periods of respirations separated from one another by short pauses.

Cheyne-Stokes respiration should be clearly distinguished from irregular breathing accompanied by pauses. In the latter form of respiration pauses occur, followed by several long gasping breaths which may gradually grow less violent and rapid or irregularly become so and cease with the beginning of another pause. Cheyne-Stokes respiration is characterized by a pause of from ten to forty seconds followed by from ten to twenty respirations which grow gradually quicker and deeper until they are dyspneic in character, both because of their violence and rapidity. During the succeeding ten to twenty respirations the movements grow progressively less violent and rapid until they cease and apnea begins. Usually the ascending and descending series of movements number about the same, but they are not always equal. The descending series are often less regular than the ascending. In the mildest cases apnea may be wanting, the ascending series of respirations may follow the descending without interruption. If, during the respiratory pause, voluntary efforts are made to breathe the whole chest is lifted by the unusual muscles of respiration, but the diaphragm and intercostals do not move.

Cyanosis is very rarely observable, although the pauses are frequent and many of the respiratory movements are shallow. Patients often complain of the wearisomeness of respiration, but not of hunger for air. In 1859, Reid (Dublin Hosp. Gaz., vi, 308) pointed out the commonly observable changes which occur in the pulse during Cheyne-Stokes breathing.

In most cases during apnea the pulse rate is quicker than during dyspnea; it will beat once or twice oftener in the quarter minute. Not infrequently the pulse is paradoxical. It is apt to be large and soft during dyspnea and small during the respiratory pause. Biot uniformly observed less arterial tension during apnea than dyspnea (*Rev. Mensuelle de Méd. et Chir.*, 1878, ii, 975). While these are the usual changes in the pulse, if any occur, it has been found in rarer instances to be slow during apnea instead of quick, and once Hesky (see Gibson, *Edin. Med. Jour.*, xxxiv) observed almost a complete disappearance of pulse beating during each respiratory pause.

In 1866, Leyden (*Arch. f. Path., Anat. und Phys. und f. Klin. Med.*, xxxvi) first called attention to the rhythmic changes that occur in the pupils during the phases of Cheyne-Stokes respiration. In very many cases, though by no means in all, the pupils become closely contracted during the pause and do *not* respond to the stimulus of light, although during dyspnea they are normal in size and respond readily to light. Contraction of the pupils usually takes place slowly and progressively, but in a few instances it has been observed to occur in slight successive spasms. Biot thinks these changes are due to variations in blood pressure, which are so often noticeable in the different phases of Cheyne-Stokes respiration. Recent observations, however, make it probable that they are not to be explained in this way, but are due to the direct influence of the nervous system upon the eye. Often, just as the pupils begin to contract, a slight convergence of the eyeballs occurs and still oftener the lids close during the period of apnea and the patient appears to be in deep sleep.

Not only do rhythmic changes occur in respiration, pulse and pupils but in a proportion of cases, as in the one that I have just described, mental processes seem to be suspended during apnea, although so soon as respiratory movements begin the mind awakes and seems normally clear. In many cases of Cheyne-Stokes respiration patients are deeply comatose and no mental variations are observable. Even in these cases, however, the pulse and eye phenomena are often seen.

In 1876, Ross (*Canada Med. and Surg. Journal*, v, 544) described a case in which general muscular rigidity occurred during each respiratory pause. Several similar cases have been described since. This is, however, not a frequent concomitant of Cheyne-Stokes respiration, and can not be regarded as one of the phenomena usually accompanying it.

In individual cases we find various combinations of these modifications of pulse, pupil and mental state. They by no means all occur coincidentally. The pulse and respiratory changes are the commonest, and next in frequency the eye and respiratory changes. Gibson (*Edin. Med. Jour.*, xxxiv) has described one case, which is interesting and important, as it throws light upon the nature of these phenomena. It was a case of meningitis, in which at regular intervals there occurred contraction and dilatation of the pupils, and coincident periods of somnolence and waking, but respiration remained normal. This case can not be called one of Cheyne-Stokes respiration, but it illustrates the fact that certain portions of the brain may be involved and produce certain of the rhythmic changes characteristic of Cheyne-Stokes phenomena, although the medulla is not affected. The reverse of this condition, which produces Cheyne-Stokes respiration, is much the commonest.

The phenomena of periodic respiration are very variable in their duration, sometimes lasting only a few minutes or hours, at other times persisting for many days or even for many weeks. An anonymous contributor to the *Lancet* (1890, i, 776) says that his father, who is advanced in years, has exhibited characteristic Cheyne-Stokes phenomena continuously for many years, although otherwise apparently well.

The dyspnea varies greatly in severity. For instance, in one case which was under my care this winter, the respiratory movements were so moderate that they caused the patient little annoyance, and he scarcely ever complained of difficult breathing. Usually, however, it is sufficiently severe to weary the patients very much, and every now and again it is intense. When respiration is wearisome and difficult it seems to demand relief by treatment. Text-books upon therapeutics and upon medicine give practically no information as to the mode of action or the utility of drugs for the relief of these peculiar symptoms. As one case after another came under treatment, I tried successively the nitrites and soporifics, thinking that they might relieve the dyspnea as they so often do that of asthma, but I soon found that their effects were uncertain, that apparently they afford relief in one case and none in another. I then tried respiratory stimulants and oxygen inhalations, but with similar results. As during the last year there came under my observation in quick succession a series of these cases, I was prompted to review the literature of the subject with care, hoping that I might there find more information in regard to the nature of the phenomena and its mode of treatment than is to be obtained from our usual books of reference. I have found the literature of the subject very large, but unfortunately, it contains almost no exact information of a therapeutic character. It is chiefly controversial in regard to the nature of Cheyne-Stokes phenomena.

When we approach the treatment of this affection we naturally ask ourselves, under what conditions does it arise and what is its nature? Cheyne-Stokes respiration has been observed as a complication of the most varied maladies, and has been provoked experimentally in very many ways. Edes (*Boston Medical and Surgical Journal*, 1879, ci, 734) and Cheyne have both pointed to certain families in whom there was apparently an inherited tendency to this peculiar form of respiration. It is rarely associated with such infectious diseases as typhoid fever, smallpox, diphtheria, cholera and whooping cough. It occurs much more frequently in cerebral affections such as meningitis, apoplexy, cerebral embolism and thrombosis, sun-stroke, insanity, hysteria, hemorrhage into the cerebellum and medulla, or aneurysm in the latter. Complicating hemophilia, hemorrhage after operations and deep anemia from other causes has been observed. It is frequently associated with certain circulatory affections, oftenest with fatty degeneration of the heart, valvular disease, pericarditis, aortic aneurysm and general arterial atheroma. At times, it also complicates respiratory affections such as bronchitis, pneumonia and tubercular disease of the lungs. It has been observed as a sequel to tracheotomy. In these affections, however, unconsciousness or semi-unconsciousness exists before Cheyne-Stokes respiration develops. It is also rarely observable in severe catarrhal affections of the gastro-intestinal tract. It occurs oftenest of all associated with chronic renal disorders, when it is usually regarded as a manifestation of uremia. It has been observed in healthy individuals who were sleeping deeply from the effect of prolonged or excessive exertion. It has also been seen when narcosis produced by morphin, chloral and the bromids was deep. In some animals it seems to be the normal mode of respiration during hibernation. It has been produced experimentally in frogs by subjecting them to very considerable changes of given, of late years, to the development of children by intelligent mothers, nurses and educators, who from time to time meet to consider the interests of children, may throw light on the normal and abnormal child's mind that may in the future make the very early recognition of defective development easier. At the present time it must be based to a large extent upon a balancing of probabilities and upon the ripe experience and the trained judgment. Fortunately there is nothing in the management or treatment of the defective child that would in any way prejudice the future of a child, in the case of a mistaken diagnosis. On the other hand much harm can be done to the prospects of development if the defective child is wrongly managed in its earlier years, and its condition only recognized when the manifest difference from its fellows becomes evident through the application of an educational system that has already worked upon it the greatest hardship.

THE CARE OF THE BABY'S EYES IN THE PERAMBULATOR.

Presented in the Section on Diseases of Children, at the Forty eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY MARY E. BALDWIN, M.D.
NEWPORT, R. I.

The matter to which I call your attention, the baby's eyes in the perambulator, is one epoch in the life of many children that seems absolutely to have been ignored. I say many children! The very poor are not luxuriating on wheels. They have a possible contact with mother earth, or with a pavement. Again they get the air on the hip of an older sister. Children born in the other extreme of worldly position are not so often in a baby cab.

In the maternity, the nursery and in the school, the young eyes have received intelligent attention with preventive suggestion and remedial treatment.

The first bright spring days are hailed by invalids and almost anybody's baby is then given a breath in the fresh air. The invalid is apt to have a veil, colored glasses, a close carriage, a sunshade, etc. For this outing the baby of fairly well-to-do parents in America may have in order of time the third special outlay for sweet daintiness. The toilet basket and the Christening robe have or have not preceded. The perambulator with its umbrella top may be the first real treasure the parents secure for the baby. It is as important as the coming-out dress of the *débutante*, or the first dress suit. What is it? Of rubber tires and the various springs, I will not speak. Would that many adults might have had an outing some glorious morning in the past three months in an enlarged baby cab. This means an intense white reflex from the blanket. much farther from the eyes than could possibly be arranged for the baby. An ever changing parasol is professedly protecting from wind and sun. What does this creation of lace and flummery really do? The average parasol for the baby cab is covered with figured white lace, or thin white material that is gathered. The lining may be fairly opaque and of neutral tint. Often the covering is of such a combination of texture and color as to give through it, in bright sunshine, a mottled light. The edge is finished by a fringe or by a ruffle, something that can wave and flop, and usually it does this so that it not only gives a changing object before the child but at the same time throws the sunshine or light of varying intensity into the face.

With the joltings from various causes, including the curbstones and the temper and thoughtlessness of the attendant, the parasol top and a white blanket to give a reflected light, there is a sorry combination. If my picture does not appeal to each one of you, I beg you to call upon your memory and put your eyes in the place of the baby's. If your attention has never been arrested by the squinting babies, will you not observe them in their perambulators?

During the short, cold and comparatively sunless days, the young child is apt to be kept indoors. The adult likes a breath of spring warmth, and gets it with an outing for the baby. From the shaded room to the unshaded street the transition is greatest for the infant, during the spring months. When summer heat comes, the care-taker will seek the shady side of the street or the protection of trees.

The ocean beach with the near sand and the far reach of sky and dancing water needs consideration, if the baby, well or sick, is to be sent to it.

Without actual demonstration, it seems most probable that an obscure etiology may often be traced to the conditions to which I have had the honor of calling your attention. Does not the probability assume so much the aspect of a certainty as to demand a widespread protest and warning. This is my reason for wishing even at this hour to enlist your interest. Grant you I certainly do, that this touches a most fruitful means of gratifying the vanity of the younger or the older mother or even of the devoted father. Twenty-five years ago, imagine if you can the horror with which we would have looked upon a dozen well-bred daintly dressed children wearing black stockings. Put a dozen daintily dressed children on the street today with white stockings and they will attract every eye.

If the parents are convinced that danger threatens the babies from the present vanities of their cabs they will accept a remedy, a prevention; make the prevention a fad, a fashion, and all is accomplished. Taking for granted that every doctor will be convinced as soon as his own eyes have been taken for an imaginary outing with those of the baby, every baby carriage will soon be dressed in opaque and soothing color, with no tilting canopy, flying frill or sharply reflecting robe.

DISCUSSION.

Dr. J. J. TAYLOR—Usually the iconoclast lays the way for the reconstructionist, but sometimes we have the iconoclast and the reconstructionist in the same individual. The Doctor has destroyed our baby carriage, but she has also given us some idea as to the proper kind of a baby carriage.

Dr. BALDWIN—I am very glad of the opportunity to speak of the remedial measures, although I can not say I have sufficiently formulated them not to be open to some *modifications*. I am told the English cabs have a top that shoves down, a good deal like the street cabs in America. Occasionally I have seen those in America. They are usually in some dark color. I am told, also, that the English cab has a dark colored robe. I think we seldom see a physician here riding with a white lap robe. Recently, in speaking on this subject, a physician said, "O, you will never get our mothers *to dress their children in* green." But I do not believe the mothers can keep the top of the perambulator in such a position as to be of any advantage to the child. I think a cover that will give a steady light is much better. I would have no lace and no frill that can be constantly changing its position. In the nursery we have been told the children should not be given things near the eyes, and that the light should not come into their eyes directly, and that at no time should they be employed with anything small. But the very first season, when the child goes in the perambulator, these rules are lost sight of. I would take away the irregular light, I would plant no flapping thing on the carriage, and I would have no white light reflected into the infant's eyes.

THE INFLUENCE OF OUR SCHOOL SYSTEM ON THE HEALTH AND DEVELOPMENT OF THE CHILD.

Presented to the Section on Diseases of Children, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY E. STUVER, M.Sc., M.D., Ph.D.
Member Colorado State Medical Society (Vice-president 1894), American Medical Association, International Medical Congress (Berlin); Active Member National Educational Association.
RAWLINS, WYO.

The strength, happiness, prosperity and stability of nations and races almost entirely depend on their hereditary heritages and their ability successfully to adapt themselves to their environment.

The whole history of man's development from the earliest times conclusively proves that his highest welfare is conditioned on the harmonious development of all his powers, physical, intellectual and moral, and that when one or more of these have been slighted or neglected, he has paid a dear penalty for such neglect.

Glancing down through the ages, we behold untold misery and innumerable wrecks caused by the violation of this inexorable law of nature. Here we see ignorance or disregard of sanitary laws followed by pestilence, disease, lowered vitality, degeneration and extinction; there we behold licentiousness, debauchery and immorality in all its varied forms, produce a similar result. Nor are the most striking examples taken from savage or barbarous peoples, but furnished by the greatest and most powerful nations the world has ever known.

The observance of these developmental laws raised Greece to the pinnacle of intellectual greatness and physical perfection; their violation reduced her to an insignificant dependency and to a position of subordination, which she is now making a gallant effort to overcome. Physical, intellectual and moral integrity made Rome the mistress of the world and the Roman name honored and feared everywhere, but the loss of the virtues which made her great was the signal for her downfall, and now there remains only the name of her former power, grandeur and glory.

Such examples as these should cause us, as a nation, to pause in the midst of our wonderful career and consider some of the dangers that threaten us, and at the same time carefully examine our bulwarks of defense and see whether they are in a condition to resist any or all attacks that may be made against them.

We have always boasted, and justly too, of our National system of popular education, and repose greater confidence, as a means of defense, in the intelligence, freedom and patriotism of our people, than in immense standing armies and monster iron-clad ships. While nearly all will admit that our public school system is a strong bulwark of defense, and has been a potent factor in molding our National character, developing our institutions and promoting our material welfare, still the question naturally arises, have these results followed as the consequence of our educational methods, or have they been largely due to the inherent force of character, mental acumen and physical integrity of the hardy pioneers who laid the foundations of our Nation, and to whom is due much of our greatness as a people?

The highest happiness and welfare of a nation or a people is in direct proportion to the highest happiness and welfare of the *great* majority of the individuals who compose it; and the greatest welfare of the individual depends upon the inheritance of a strong, well balanced organization and the symmetric and harmonious development of all his powers; in short, in order to attain the most complete living he must be perfectly adjusted to his environment. To accomplish these results an educational system must provide, in the first place, for a strong physical organization on which to work. Sanitary, hygienic and dietetic laws should be thoroughly understood and their principles carefully inculcated. Every parent and teacher should be strongly impressed with the truth that a "sound mind in a sound body" is a *sine qua non* in every case, if enduring results are desired or expected. Every one, and especially teachers, should understand that plain, nutritious and unstimulating food, an abundance of sleep, and plenty of free, unrestrained exercise in pure air, away from the formality and routine of the schoolroom, where the spontaneous activities are given free play, are of the greatest possible value to the child. They should not only know, but put into practice, the truth that proper food, plenty of oxygen, and frequent periods of relaxation in which to rest and change the activities of the brain, are of infinitely greatar value to the child than the details of geography or history, or the memorizing of rules of grammar or arithmetic, frequently drawn from principles they do not understand. Then, too, teachers and all those who have the direction of the intellectual and moral training of children, should have a clear and comprehensive knowledge of the laws and principles underlying and governing the development of the brain, as well as the mental and moral faculties of the child. They should know that the brain of the child, as compared with that of the adult, contains a larger percentage of water, is more unstable, more easily irritated, and that as a consequence, long continued, monotonous work not only fails to strengthen it, but, on the contrary, weakens the mind, besides producing irritation of the brain, with a lowering of the vital powers and retardation of the physical development. They should understand that the motor centers, which preside over and control muscular movements, act much as storage batteries, that is, they store up nerve force, which is almost constantly being discharged and producing muscular movements. The proper development of the muscular system being the foundation on which muscular strength and integrity depend, nature has wisely, by the automatic discharge of nerve force, to a large extent removed muscular development from our volitional control. We might just as well try to compel a normal, healthy child to stop breathing, as to remain quiet for any great length of time. The nerve force accumulating in its motor centers has just as specific and important a function to perform as that which regulates the activity of its respiratory organs. If teachers understood this fundamental physiologic truth, together with the fact that the inhibitory brain centers, as well as the paths of association whi[illegible] connect them with the motor centers, [illegible] veloped condi[illegible] thereby [illegible] nearly force in muscular movement, and that when the attempt is made to frustrate this provision of nature the effort at inhibition not only requires much brain power, which should be used in quiet thought and study, but that it produces irritation of the brain and weakens the mind, they would not commit the very common error of trying to compel young pupils to concentrate their attention on one subject or remain quiet for a long time.

Teachers who understand the natural order of evolution of the faculties can assist nature in directing the mind in proper channels and help strengthen and develop the various mental powers at the proper time and in the proper manner. Activity is the normal healthy condition of the human mind, and if this activity be properly directed mental work should be a constant joy, a source of the greatest pleasure and happiness to the learner. Show me a school where the pupils dislike their work, where everything is regarded as a disagreeable task and evaded or performed as a matter of routine, and I will show you a school where dreary drudgery and dead formalism have taken the place of generous enthusiasm and noble aspirations; where the laws of mental and physical growth are outraged and the moral nature is being warped and distorted, and in charge of that school you will find a teacher entirely unfitted for his or her work and who is lowering one of the grandest vocations to the level of a mercenary calling.

Every educator should appreciate the fact that in its development the child is an epitome of the development of the race. It passes through savage, barbarous and semi-civilized phases of development with many of their attendant impulses and passions before reaching that culture and refinement represented by our best civilization. In view of all these facts the proper training and education of a child is a most difficult thing and demands on the part of the teacher natural ability for the work, a thorough education and careful professional training, besides an accurate and comprehensive historic knowledge of the mental and moral evolution of the race and a careful observation and study of these faculties in the child.

While educators are being profoundly stirred on this subject and "child study" is receiving much attention and creating great interest, still the fact remains that the great mass of teachers know very little about it: indeed, it is a deplorable fact that the great majority of teachers in our public schools have never had adequate professional training of any kind (only about 15 per cent. have taken a course of training in normal schools, see *Forum*, April, 1896, page 179), and many lack that thoroughness of education necessary to make them first-class teachers. Under these conditions, is it any wonder that the courses of study formulated and the methods of instruction pursued have been either injurious, barren of results or failed to produce that highest good which should be the aim of all education.

To obtain a consensus of opinion on the influence of our school system on the health and development of the child, I addressed to about one hundred and fifty of the leading educators and physicians of the country the following questions:

1. Do you think our present comprehensive course of study is best calculated to develop the highest physical and intellectual powers of the child?
2. How long do you think continuous school sessions should last?
3. What is the longest time that should be devoted to a single recitation? *a.* In primary grades; *b*, in grammar grades.
4. How often should pupils have recesses or periods of relaxation?
5. Which do you think are more beneficial, open-air recesses with spontaneous play, or formal indoor exercises consisting of calisthenics, etc., and why?
6. To what extent does the practice of denying pupils the privilege of attending to the calls of nature or of punishing them for the exercise of this privilege (by making up for the time so lost, etc.) exist in the schools? *a.* What do you regard as the moral effect of such a practice on the child? *b.* What physical evils may or do follow it?
7. What effect does "home" study, outside of school hours, have on children, and especially on girls during puberty?
8. What should be the outside limit of such study for: *a*, grammar school pupils; *b*, high school pupils?

One hundred and five answers were received: Sixty-nine from educators, including college presidents, professors in colleges and normal schools, superintendents of city schools, principals of graded schools and others eminent as educators; also thirty-six from physicians who occupy professorships in our leading medical colleges or have distinguished themselves as general practitioners or specialists whose work is among children, or who have large opportunities to observe the effects of school work upon the health of those who have recently passed through or who are now pursuing a course of study in the schools of the United States. As you will notice, the answers come from all sections of the country, and as a consequence the results of the investigation which I herewith subjoin, do not possess a mere local significance.

Answers to No. 1.—Sixty-three of the sixty-nine educators answered this question as follows: Yes, fifteen; no, twenty-nine; doubtful, eighteen, with one no to first part and yes to the second part.

Prof. Joseph Baldwin, LL.D., Austin, Texas: No. Many modifications are demanded.

Prof. Edward Brooks, LL.D., of Philadelphia, Pa.: Yes. The course in the elementary schools is not too comprehensive and does not interfere with the physical development of the child.

President George Stockton Burroughs, LL.D., of Crawfordsville, Ind.: No. Too many subjects are handled at once; the physical neglected.

Prof. William A. Cate, M.S., of Fountain City, Tenn.: Too many studies are carried at one time. I do not find so much fault with the comprehensiveness of the courses of study, however, as I do with the everlasting cramming in teaching.

President Alston Ellis, LL.D., of Fort Collins, Colo.: No. Course of study in higher grades too pretentious.

President Charles W. Eliot, LL.D., of Cambridge, Mass.: Courses are now in stage of transition, are being revised and enriched and will result in a comprehensive and better course.

Principal J. M. Green of Trenton, N. J.: I do not. I think it contains too many subjects, as generally laid out.

Supt. J. M. Greenwood, A.M., of Kansas City, Mo.: In general the schools are overcrowded with studies.

President G. Stanley Hall, Ph.D., of Worcester, Mass.: It needs great reconstruction.

Prof. Mark W. Harrington, LL.D., of Seattle, Wash.: Probably best for pupils treated collectively. Better means could be applied to pupils treated individually.

Supt. L. H. Jones of Cleveland, Ohio: I am a believer in liberal and comprehensive course of study.

A. A. Johnson, D.D., of Laramie City, Wyo.: Yes, if proper attention is given to hygiene and physical exercise.

Prof. Joseph W. Mauck, LL.D., of Vermilion, S.D.: I believe it would be better if less comprehensive and more intensive; more thorough grasp of a few subjects and less distraction and anxiety from a multiplicity of studies.

President George L. Osborne, LL.D., of Warrensburg, Mo.: The early part of the course deals too much with books and not enough with nature. It is also defective in its cultivation of the power of expression.

William H. Payne, LL.D., of Nashville, Tenn.: There is a tendency to injurious high pressure.

Col. F. W. Parker of Chicago.: There are a great number of courses of study and few are adapted to the growth of the child.

Mrs. Frances E. Ramsey of Westport, N. Y.: Emphatically, no! There is danger of superficiality as well as physical degeneration through feeding the brain at the expense of the body.

President Charles Super, LL.D., of Athens, Ohio: I do not, most emphatically.

Nathan C. Schaeffer, LL.D., of Harrisburg, Pa.: Everything depends upon the teachers employed.

Charles F. Wheelock, B.S., of Albany, N. Y.: No. We teach too much and permit the child to develop too little.

Rev. F. R. Wotring, D.D., of Berthoud, Colo.: No. Too much pouring in and not enough drawing out, though there has been a great improvement in recent years.

President Irwin Shepard, A.M., Ph.D., of Winona, Minn.: Yes, if wisely administered.

Thirty-five physicians answered this question (No.1) as follows: Yes, two; no, thirty-two; doubtful, one. The following are some of the opinions expressed:

Prof. Henry M. Brown, M.D., of Cincinnati: Not by any means; too hard on the nervous system.

Prof. N. P. Dandridge, A.M., M.D., of Cincinnati: No. I regard our public school system as defective in many ways.

Prof. N. S. Davis, M.D., LL.D., of Chicago: No; because it taxes the mind with too many studies and prevents thoroughness in any.

George M. Gould, M.D., of Philadelphia: Not by any means. Our modern system of education is the offspring of vanity and sin, for which our future world will justly curse us.

Prof. C. H. Hughes, M.D., of St. Louis: No. It is too exhaustive, overtaxes the perceptive powers and dwarfs the reflective. The tension on the physical centers is beyond their responsive powers and powers of body and endurance.

Prof. Frank Parsons Norbury, M.D., of Jacksonville, Ill.: I am opposed to the present method of conducting primary grades, very large classes and crowding together.

Prof. C. D. Palmer, M.D., of Cincinnati: No. One of the most serious effects of our modern school education, especially in the more advanced grades, is the multiplicity of studies crowded into any course, for the result is that a very imperfect and superficial information is obtained with nothing done in a thorough manner. A few things learned well are infinitely better than many learned superficially. Bad habits of mental training are induced by skimming over branches. Good habits of study and strength of mental discipline come only from thoroughness.

Prof. Theophilus Parvin, M.D., LL.D.. of Philadelphia: I do not believe in a common education for boys and girls. They have or ought to have different work or calling in life and the education should not be the same in many departments of study. Of course, it follows that co-education can not be. On moral grounds, too, I am unfavorable to such education. Not only sex but the individual is disregarded in our system of public education.

Prof. Thad. A. Reamy, M.D., LL.D., of Cincinnati: No. They are not taught to think and observe.

W. H. Short, M.D., of La Grange, Ind.: There are too many branches in one grade: too much required in all grades, especially primary grades, *e.g.*, arithmetic contains too many written exercises and examples which never occur in business, and fractional numbers of large and unusual terms which weary and bewilder, and when written analysis is required a child of only average ability, in almost every case, is compelled to accomplish this at home. If we had teachers of discretion who would cut out half of the text-book and instead give the classes, simple practical business questions, both mental and written, much would be gained. Instead of some conception of the simplest laws of mathematics, children are misled with rules and puzzled by hard questions until they neither know what they are trying to learn nor what powers they are trying to use, and so in other branches. *Too much attention is given to details.*

Henry Ling Taylor, M.D., of New York City: Not as I am acquainted with it.

Henry E. Tuley, A.B., M.D., of Louisville: The curriculum in the public schools in this city is very good.

De Forest Willard, M.D., of Philadelphia: Fewer branches would yield better results.

Prof. James T. Whittaker, M.D., LL.D., of Cincinnati: I think there is too much study from books and too little from nature.

Wm. Jay Youmans, M.D. (Editor Popular Science Monthly), New York City: No. It includes too much, forestalling the exercise of the thinking faculty. I am not an admirer of our school system as now organized. It is artificial to the last degree; while healthy development, both bodily and mental, is a natural process that is oftener defeated than promoted by the school.

Augustus P. Clarke, A.M., M.D., of Cambridge, Mass.: Not for the average child.

Prof. Leonard Freeman, B.S., M.D., of Denver: No. There is too much systematic study and too little systematic physical culture.

Prof. J. A. Larrabee, M.D., of Louisville: The course of study and requirements between eight and twelve years is too laborious, exacting and voluminous.

Answers to No. 2.—One hundred educators and physicians answered this question, and while there is considerable diversity of opinion among them the average length of a session without outdoor, open air recess, advocated, is from one to one and one-half hour. Many insist that the sessions should be shortened and more time given to physical culture.

Answers to No. 3.—Just one hundred answers were likewise received to this question, and while there is considerable divergence between them, the great majority advocate recitations, in the primary grades, of from ten to twenty minutes in length, and in the grammar grades from twenty to thirty minutes. It is urged, very justly t [illegible] by many of the respondents that the l [illegible] tation should be governed to a large [illegible] ct, t [illegible] d of instruction and the kind of teacher in charge of the class; that a good teacher would be able to maintain the interest of the pupils for a longer time and attain good results, while under the charge of a poor teacher, this interest would not be secured, they would soon tire and be more injured than benefited.

In this connection I desire to insist that whenever the children of a class in their efforts to follow the recitation, become tired, or it requires a strong effort of the will to keep their attention on the work in hand, it is time to stop. If this limit be exceeded the unstable brain will be injured and infinitely more harm than good be done. The custom of requiring pupils of 11, 12 or 14 years of age to spend two hours or more continuously on a single recitation, review or examination of one subject as is sometimes done, is not only a gross violation of all mental laws and is *prima facie* evidence of ignorance or heartlessness on the part of the teacher, but is at the same time barren of results; because it is a well established fact that impressions made on a tired brain are very evanescent in character and the effort required to concentrate the attention in such a condition has a very enervating effect on the mind.

Answers to No. 4.—The importance of relieving the strain on the brain and allowing it to equalize its energies; that is permitting the stored up nerve-force of the motor centers to discharge itself in muscular activities while the higher brain centers are resting and accumulating force to carry on their proper work, is being recognized by the best educators and physicians who advise frequent periods ef relaxation and play.

In response to this question I quote the following:

Prof. Joseph Baldwin, LL.D., of Austin, Texas: Every hour.

Prof. Edward Brooks, LL.D., of Philadelphia: Each hour to once in each half daily session, according to grade.

Pres. Chas. W. Eliot, LL.D., of Cambridge, Mass.: As often as once an hour in all grades.

Supt. J. M. Greenwood, A.M., Kansas City: Two regular recesses of fifteen minutes.

Pres. Geo. L. Osborne, LL.D., of Warrensburg, Mo.: Very young pupils at least once in thirty minutes; upper grades once per hour.

Pres. G. Stanley Hall, Ph.D., of Worcester, Mass.: If practicable, a little every hour.

Supt. L. H. Jones, of Cleveland, Ohio: Once in about one hour.

Prof. G. W. Patrick, Ph.D., Iowa City: Every hour.

Col. F. W. Parker of Chicago: A short period, between every two recitations, of music and gymnastics; fifteen minutes outdoor play in the morning session.

Mrs. Frances E. Ramsey of Westport, N. Y.: After each recitation if practicable.

Prof. W. J. Stevens, M.A., of Carthage, Mo.: At least every forty-five minutes.

Prof. Wm. H. Smiley, A.B., of Denver: Best work would be done with opportunity for free movement every hour for five minutes.

Pres. Z. X. Snyder. Ph.D., of Greeley, Colo.: Every hour or so.

Nathan C. Schaeffer. LL.D., of Harrisburg, Pa.: Twice each day and noon intermission.

Prof. Irwin Shepard. A.M., Ph.D., of Winona, Minn.: Every hour.

Pres. Alfred Holbrook, of Lebanon, Ohio: Every hour a short recess of ten minutes.

Prof. N. S. Davis, M.D., LL.D., of Chicago: Once in the middle of each daily session.

Prof. J. T. Eskridge, M.D., of Denver: Every hour, or at most every two hours.

Geo. M. Gould, M.D., of Philadelphia: Every hour.

I. B. Parkins, M.D., of Denver: At least once in afternoon and forenoon.

Prof. James T. Whittaker, M.D., LL.D., of Cincinnati: In the middle of each session.

Elizabeth K. Matthews of Des Moines: At the close of every lesson or study period.

Answers to No. 5.—In the whole range of educational subjects there is no question more fraught with important consequences to the child than that of proper sanitary surroundings and ample provision for healthful outdoor exercises. As previously indicated the brain of the child is unstable and easily irritated; nerve-force rapidly accumulates in the motor-centers and unless frequent opportunity be given for its discharge in muscular movements, the attempt to inhibit the movements by will power, will not only set up irritation of the brain, make the child peevish and unamiable, injure its health and interfere with its proper physical development, but will at the same time weaken the mind and defeat the very object for which long sessions are intended, viz., the accomplishment of the largest amount of work in a given time.

Oxygen is necessary to produce nerve-force (Spencer: "Principles of Biology," Vol. I, p. 50), to stimulate the respiration and the circulation of the blood, to develop the muscular system and to destroy the poisons constantly accumulating in the body. No room with from forty to sixty pupils can be occupied much over an hour and the air be fit to breathe without dangerous draughts being created; consequently, pupils should have a fifteen minute, open air, outdoor recess in the middle of each long session. During this recess the windows should be thrown open and the room thoroughly ventilated, the foul emanations eliminated and the air vitalized. This outdoor exercise is best for the child because it removes him from the monotony, formalism and routine of the schoolroom and enables him, yes, compels him to inhale full draughts of nature's life-giving element, pure air, to free his system from accumulated poisons and spontaneously to develop his powers and adjust himself to his environment. A properly conducted recess not only increases the sympathy and fraternal feeling between pupils, increases their physical strength and enlarges their intellectual and moral horizons, but draws them closer to Mother Nature, the source from which to derive inspiration. The recess too gives pupils an opportunity to attend to the calls of nature which under other conditions would be neglected, because, as pointed out by Durante (*Medical Age.* Oct. 10, 1896, p. 601) "the sigmoid flexure in children is of much greater length than in the adult; the nervous forces also are not yet as well regulated; so the child does not feel the need of an evacuation" and, therefore, children are more apt to put off or disregard these calls of nature than they are to abuse their privileges if permitted to leave the room whenever necessary.

The recess too, to a large extent, prevents withdrawals from the room during the school sessions and in this way much disturbance is avoided and good order promoted. The objection to the recess on the ground of immorality is, in my opinion, not well founded, because there is much greater danger of immoral practices being carried on when a few pupils are excused from the school at the same time during the sessions than when all are let out together at the general recess. I do not wish to be understood as being opposed to calisthenics and gymnastic exercises. On the contrary, I regard them as of very great value and deserving of a place in every school. What I do wish to insist on, however, is that they should be used in connection with, but not displace, the regular outdoor recess. In the advanced sheets of his new work, kindly sent to the writer, the distinguished author and educator, Prof. Joseph Baldwin of Austin, Texas, writes as follows:

PLAY AND GYMNASTICS.

Play is eminently hygienic.—"Recreation makes the best work possible. The kindergarten by utilizing play has made a large contribution to the well being of the race. Work fatigues, exhausts the brain cells; play is recreation for it is free, spontaneous activity. It breaks the spell of work and care. From infancy to age play is a boon to all workers. A self while taking recreation relaxes effort and roams fancy free. Thus the tired brain is given time to recuperate. The men of thought as well as the men of action, double their efficiency by taking regularly helpful recreation."

School work is education when pupils are fresh.—"Drudgery hurts and does not help. Work and then play is the divine plan. We may easily quadruple the value of our schools by studying to keep the pupils fresh. Strong men find recreation a necessity; how much more must immature pupils play as well as work and thus grow. He who helps to lead the school world to play wisely deserves to be crowned as a benefactor."

Recess at the close of each hour is the perfect economy.— "The hygienic and educative benefits of the hourly recess are incalculable. Young children soon become fatigued and so we make their periods of work very brief. The periods of work are lengthened as the pupils advance. The fatigue limit is a great practical study. Much may be done to keep pupils fresh by having easy work follow difficult work. Change rests, but frequent periods of absolute freedom are indispensable. In schools of the future it is believed a recess of ten minutes will be given at the end of each hour."

Play in open air is most hygienic.—"Suitable play grounds with the best play-provoking facilities may safely be counted among the most hygienic agencies. All real play is essentially free and spontaneous, yet at no time is a wise supervision more important than during play. Hurtful plays may be discouraged and the most helpful plays fostered. The teacher feels the play impulses and so guides by suggestion without abridging freedom and spontaniety. Well ventilated, well lighted and commodious play rooms for use during inclement weather are remarkably helpful when the supervision is judicious. However great the cost, these play rooms pay largely in increased pupil vigor."

Systematic physical culture is indispensable.—"In our best schools physical culture goes side by side with mental and moral culture. Graded physical exercise gives pleasure, gracefulness and vigor. During the pauses pointed suggestions are given in practical hygiene. The gymnastic exercises when adapted to the pupils and well managed are educative as well as hygienic. They develop habits of exact obedience, train pupils to work in harmony with others and give artistic command of the body. *Gymnastics require considerable will effort, and hence do not take the place of the spontaneous plays of the recess.* (Italics ours.) The Germans emphasize systematic gymastics but neglect play. The English exalt play but neglect systematic physical culture. The Americans and the French after the fashion of the Greeks, emphasize both play and gymnastics."

In contrasting romping and calesthenics Prof. Frank H. Hamilton (see *Lancet-Clinic*, Oct. 31, 1896, p. 477) speaks as follows: Calisthenics may be very genteel and romping very ungenteel, but one is the shadow, the other the substance of healthy exercise. Girls need health as much, nay, more than boys. They can only obtain it as boys do, by running, tumbling; by all sorts of innocent vagrancy. At least once a day girls should have their halters taken off, the bars let down and be turned loose like young colts.

Out of 105 answers to this question all except four strongly advocate out-door exercise or a combination of calisthenics and the old-fashioned recess. Following are some of the replies received:

Henry S. Baker, Ph.D., of St. Paul: In city schools calisthenics are infinitely better.

. Prof. J. E. Brate, A.B., of Fostoria, Ohio: The former; they tend to relieve necessary formality of room and give nature's best tonic, pure air.

Prof. Warren Darst of Ada, Ohio: Open air, better air, usually more hearty, freer minds, more restful, therefore more free from restraint. Cultivate a free spirit favorable to free institutions, more self-control and self-reliance among pupils.

Prof. C. C. Emigh of Fort Collins, Colo.: Out-door, wild, free, innocent, natural play at what pleases the individual pupil best. Calisthenics require close attention.

Pres. Alston Ellis, LL.D., of Fort Collins, Colo.: I favor both, the open-air recesses preferred. Calisthenics at close of recitation.

Pres. Chas. W. Eliot, LL.D., of Cambridge, Mass.: I would insist on both. If I could have but one I would prefer recesses with spontaneous play.

Prof. L. C. Greenlee, A.M., of Denver: Open-air recesses: 1. Pure air. 2. Not so fatiguing. 3. More natural to child, and relaxation more complete.

President Graves, A.M., Ph.D., of Laramie City, Wyo.: Open-air recesses and all pupils, unless real invalids, should be obliged to go out every time. I do not believe there is anything like getting good oxygen into the lungs and getting the benefits of sunshine.

Supt. J. M. Greenwood, A.M., of Kansas City, Mo.: Open air; no indoor recess can take the place of the regular old-fashioned spontaneous recess.

J. H. Miller of Lincoln, Neb.: Out door, if possible to have close supervision as in country schools; if otherwise these are dangerous to morals and not needed, as children have nothing to do but play before and after school.

Supt. J. H. Millspaugh, A.B., M.D., of Salt Lake City, Utah: Open-air recesses. Freedom and spontaneity are essential to perfect relaxation, yet rightly directed calisthenics will serve a p[illegible]ose not met by recesses.

Pres. Geo. L. Osb[illegible] sburg,
Open air with spc[illegible] dir
Greater freedom, [illegible] s,
results. Cal[illegible] r va

and systematic exercise with a view to regularity of movement and discipline.

Prof. John H. Philips, A.M., of Birmingham, Ala.: Both essential; first must be had, second should be; first, health; second, physical grace and strength.

Prof. W. B. Powell, A.M., of Washington, D. C.: The latter, because the exercise can be directed to known wants. The child has free undirected exercise enough without this.

Miss Estelle Reel, State Superintendent of Public Instruction, Cheyenne, Wyo.: Open-air recesses, because more helpful.

Prof. Wm. H. Smiley, A.B., of Denver: Open-air recesses with spontaneous play. The child, instinctively, unless abnormal, will harmonize his bodily organism with his environments better than any one can do it for him.

Pres. D. E. Sanders of Fort Scott, Kan.: Open air. Greater freedom, purer air, more interest.

Pres. Z. X. Snyder, Ph.D., of Greeley, Colo.: Open air by all means.

James Russell Parsons, Jr., and Dr. Roland Keyser of Albany, for Board of Regents, New York: Recess with play, because it affords complete and natural recreation.

Albert E. Winship of Boston: I doubt the utility or necessity of a recess. Indoor recreations, singing, calisthenics, etc., would seem all sufficient.

Pres. Irwin Shepard, A.M., Ph.D., of Winona, Minn.: Open-air recesses once each session and calisthenics between recitations.

S. Henry Dessau of New York City: Open air by all means. It restores oxygen to blood and gives vent to pent up energy.

Prof. Chas. Dennison, A.M., M.D., of Denver: Open air always in pleasant weather.

Joseph Eastman, M.D., LL.D., of Indianapolis: By all means open-air recesses with spontaneous play. Exercises by rule keep the mind on a strain. Chest expansion is better facilitated by outdoor exercise and chest expansion determines the capacity of any individual for physical or mental exertion.

Prof. F. Forchheimer, M.D. of Cincinnati: The former. We know that the air in schoolrooms is not the best, therefore as much fresh air as possible.

Prof. I. B. Perkins, M.D., of Denver: Always outdoor. Indoor exercises are of little value; fresh air is what they need.

Prof. Henry Sewall, M.D., Ph.D., of Denver: A combination of both. Calisthenics should be practiced in the open air when possible and are then preferable if one mode of recess must be chosen.

P. A. Walling, M.D., of Park Rapids, Minn.: Open air and plenty of it. Reasons: This gives greater freedom and allows the minds to come in touch; also it brings out the slow ones, does away with the idea of a recitation as the set exercises are apt to be viewed.

Prof. James T. Whittaker, M.D., LL.D., of Cincinnati: Open air and spontaneous play because of better ventilation and because there is no tonic like pleasure: a task is no pleasure.

Wm. Jay Youmans, M.D., of New York: Freedom in the open air because it is natural and superior to any artificial arrangements that can be devised.

Prof. Augustus P. Clarke, A.M., M.D., of Cambridge, Mass.: My experience leads me to doubt very much the pretended benefits of calisthenics and gymnastic exercises, which serve to make the pupil be more like a machine than a living being. Outdoor exercises: they favor spontaneous activities.

Harriet E. Garrison, M.D., of Dixon, Ill.—Open air. The machine system of our schools is crushing out spontaneity from children.

Hon. John J. Lentz of Columbus, Ohio: Open air for reasons that must be obvious.

Pres. Alfred Holbrook of Lebanon, Ohio: I would prefer both alternately enjoyed. Indoor exercises when weather is inclement.

Elizabeth K. Matthews of Des Moines, Iowa: By all means the outdoor. The child gets the benefit desired, perfect freedom without restraint, hence normal development.

Prof. J. A. Larrabee, M.D., of Louisville, Ky.: Primary grades, five minutes recreation in schoolroom after each recitation. For all grades, fifteen minutes recess in the middle of the forenoon and afternoon sessions. Morning session to begin at 8 A.M. and close at 12 M.; afternoon session to begin at 2 and close at 4 P.M., thus enabling all children to go home for dinner. The recesses, except the recreation above mentioned, should always be outdoors, untrammeled and unrestrained. The windows of the rooms should be thrown open in pleasant weather. Calisthenics and all rhythmic exercise, whether by system or music, tend to continue thought and brain exertion and is not therefore complete relaxation.

(To be continued.)

ABNORMAL RESPIRATION IN INFANTS FROM OBSTRUCTION IN THE UPPER AIR PASSAGE.

Presented to the Section on Diseases of Children at the Forty-eighth Annual Meeting of the American Medical Association, at Philadelphia, Pa., June 1-4, 1897.

BY JAMES J. CONCANON, M.D.
PHYSICIAN FOR DISEASES OF CHILDREN, NORTHWESTERN DISPENSARY; LARYNGOLOGIST, ST. BARTHOLOMEW'S CLINIC; ASSISTANT SURGEON, N. Y. EYE AND EAR INFIRMARY.
NEW YORK, N. Y.

Normal infantile respiration in sleep is quiet, noiseless, save for the soft low inspiratory murmur, always nasal, chiefly diaphragmatic. During the first month its rhythm is irregular, there are frequent pauses and at times it is deeper, as in the Cheyne-Stokes variety. Its rate varies from 30 to 45. At the end of the third year it is regular and has a rate of 24. The rhythm is changed by very slight impressions. The movements seen are the ample ones of the abdomen, the lesser ones of the thorax and those of the nasal alæ. There is no drawing in of the fleshy portions of the thorax, the mouth is closed and the act of nursing can be completed without interruption.

Widely differing in its symptoms from that due to pulmonary or bronchial affections, abnormal respiration from obstructions in the upper air tracts is more difficult to trace to its cause, but is more amenable to treatment. Many fatal cases have shown that errors of diagnosis are common. Only recently has it become generally known that nearly all cases of croup are true diphtheria. Deaths from foreign bodies in the larynx or trachea, or from growths therein, could have been prevented had these not been mistaken for croup.

There exists hardly any other affection so dangerous and distressing to the patient, alarming to his family, or trying to the physician as obstructive dyspnea; nor is there any in which treatment is more effective. In no other condition is the skill of the surgeon or the ability of the physician so evident. Antitoxin is the greatest medical triumph of the nineteenth century, and intubation and the recognition and removal of obstructive growths are amongst the most brilliant of surgical achievements. Occuring with great frequency in early childhood, respiratory obstruction may be regarded as one of the most important of pediatric subjects. The condition may last for moments or for years; life may be ended by it in a few moments or made unenjoyable for months or throughout its whole duration.

The symptoms, effects and treatment vary according to the nature and degree of the obstruction, and with its situation, which may be in the nasopharyngeal, the pharyngeal, or the laryngotracheal portion of the air tract. The first of these divisions extends from the anterior nares to and including the retronasal space; the second, from the level of the palate to that of the larynx; the third, from the mouth of the larynx to the lower end of the trachea. Briefly, impediments in the nasopharyngeal portion cause mouth-breathing; in the pharyngeal, snoring, and in the laryngeal stridulous respiration.

Of the three, that last mentioned is by far the most important.

LARYNGEAL OBSTRUCTION.

Laryngeal obstruction figures largely in infantile mortality. Phonation being one of the principal functions of the larynx, an altered or lost voice will be one of the earliest symptoms of obstruction.

The larynx being also the gateway of the respiratory regions, its partial closure interfering with the influx of air soon causes dyspnea with laboring inspiratory movements and noisy breathing.

Causes and symptoms.—The causes of laryngeal dyspnea in infants are numerous. Dividing them into six groups, it will be convenient to study, first, their nature and symptoms, and afterward their diagnosis and treatment.

Malformations of the larynx may cause congenital aphonia, hoarseness or dyspnea. There have been found membranous webs joining the vocal chords, and elongations of the arytenoid cartilages, preventing proper closure of the glottis and giving rise to whispering voice. The epiglottis in infants is folded longitudinally, approximating the aryteno-epiglottic folds. In some cases this causes so much narrowing of the entrance to the larynx, as to give rise to what has been called chronic infantile stridor, which is accompanied by crowing inspiration that at times becomes shriller as the dyspnea increases and again subsides to the low-pitched stridor which is always present even in sleep. One case of this affection has been under the author's observation since birth. Although there is a great improvement, noisy inspiration with occasional attacks of dyspnea exist still, the child being 3 years old. Even slight congestion may be very dangerous in these cases.

Laryngeal growths are nearly always papillomatous in infancy, fibroma being rare and myxoma and cysts rarer still. The last named are sometimes found on the epiglottis. Growths give rise to dys- or aphonia, cough and dyspnea. The number and intensity of the symptoms depend upon the size, situation and character of the tumor. Granulations from tracheotomy wounds may be a cause of obstruction. With pedunculated subglottic growths the symptoms may be intermittent. Systemic effects, anemia and failure of development from imperfect respiration are present in proportion to the duration of the obstruction.

Foreign bodies according to their nature, size and location, give symptoms varying from the mere sense of their presence to the most distressing dyspnea or instant death. In infants they nearly always cause dangerous stenosis, although in out-of-the-way places they may be present for a long time without giving rise to any pronounced symptoms, but may at any time cause fatal obstruction from edema or displacement. Pointed bodies, pins and fish-bones, and prickly ones, as sand-burs, usually fasten themselves in the larynx. Fish-bones may be fastened across the glottis without serious symptoms unless edema occurs. Pieces of meat or other food, vomited or swallowed, entering the larynx are perhaps the most dangerous and frequent of foreign bodies ordinarily met with in infants. Smooth, roundish bodies. such as small glass beads, buttons and fruit stones may pass into the trachea. Bronchial glands have also been found therein. If these do not pass into the bronchi they may remain loose in the trachea, a source of great danger from being subsequently wedged into the glottis.

Inflammations of the larynx, idiopathic or caused by the exanthemata, malaria, aphthæ, erysipelas, pertussis, typhoid, influenza, syphilis, tuberculosis, urticaria, erythemanodosum, pemphigus, traumatism, cold, inhalation of steam or of caustics and foreign bodies cause edematous, membranous, spasmodic or cicatricial stenosis.

Cicatrices are the result of congenital syphilis, sometimes of inhaled steam or caustics. Stenosing infiltration is extensive in syphilis, burns and tuberculosis. Spasmodic stenosis may result from congestion or inflammation, the local condition acting as an irritant to excite closure of the glottis.

Membranous exudates occur not only in diphtheria but also with scarlet fever, influenza and aphthæ.

Stenosis depending upon causes that act through the laryngeal nerves are frequent in infancy, at which period the controlling centers are undeveloped and motor response to all irritations is very active. Apart from the spasm occurring with congestion or inflammation of the larynx, reflex spasm may be due to dentition with its slight cough, pertussis with its inspiratory dyspnea, or to tetany or rickets, which are not seldom fatal. Other reflex causes are mediastinal tubercular glands, retro-esophageal abscesses, or hypertrophied thymus gland pressing upon the recurrent laryngeal nerve. Others yet are foreign bodies in the ear, nose or tonsils. Adenoid growth of the nasopharynx and elongated uvula are not infrequent causes. In some cases of rickets these spasmodic attacks of dyspnea are easily excited. One case happened in the author's practice where tetany and laryngismus stridulus coexisted. An attack fatal in half a minute, was caused by feeling the pulse. In chorea the inspiration has a peculiar wavy character which may be due in part to the intermittent contractions of the laryngeal muscles. Paralysis of the larynx often follows diphtheria and may be a cause of severe continuous dyspnea. Unilateral abductor paralysis gives dyspnea upon exertion only. It may result from compression of the recurrent laryngeal nerve. Suffocation from particles of food is likely to happen.

The pressure upon the larynx or trachea of retro-esophageal abscesses, enlarged cervical glands, hypertrophied thymus gland or foreign bodies in the esophagus may be causes of fatal dyspnea, as may also the peritracheo-laryngeal abscesses described by Massei.

Diagnosis.—Notwithstanding that the diagnosis of some of these laryngeal causes of dyspnea is often a matter requiring no small degree of ability, it would be more often successful if it were generally known that the examination of the larynx in infants is not at all so difficult as has been believed. It is not, as in the case of adults, a matter of training the patient, but one of gentle force, properly applied. Probably not one physician in fifty examines the infant larynx. Direct and laryngoscopic examination of the larynx should be practiced until skill is acquired. No one can be considered an adept in the treatment of diseases of childhood who is not proficient in the employment of modern methods for the diagnosis and treatment of the diseases and abnormalities of the upper air-passages. No careful physician commences the treatment of an infant without examination of at least the fauces. In three-fourths of the cases, as we get them, the upper air-passages are involved. With the patients head well back and the tongue drawn forward, by means of the little finger placed beside the epiglottis, or better yet, with the spatula of Escat, the knobbed forks of which fit into the sinus pyriformis, the larynx can be opened to laryngoscopic and, in many cases, to direct examination.

In the diagnosis and treatment of the first three classes of causes of stenosis, malformations, tumors, and foreign bodies, laryngoscopy is indispensable. Acute stenoses have diverse causes but symptoms much alike. Moreover, the history is often obscure. While unobserved the infant may have swallowed a pin or button, or inhaled steam from the spout of a kettle and can not or will not give an account of it, hence, examination of the larynx is necessary for intelligent treatment. Bodies in the trachea may give symptoms easily mistaken for those of croup. The laryngoscope will often fail here and then recourse must be had to the Roentgen rays, which method, cryptolaryngoscopy, has been successfully used for the location of foreign bodies in the air tracts and esophagus.

Inflammatory conditions are distinguished from others by the presence of fever, the symptoms of the causative disease or the history of the causative accident. It is well to remember that with stenosis occurring in the course of acute diseases, the Klebs-Loeffler bacillus can often be found. In very severe stenosis occurring in the course of measles or scarlet fever, it is much better to administer antitoxin at once, which will often serve not only to cure but in so doing will indicate the true cause while awaiting further confirmation of the bacteriologic examination. Stenosis from inhalations of steam or other irritants can be ascertained by examination of the fauces and epiglottis, where their action is quickly manifested, urgent dyspnea and dysphagia coming on rapidly as the result of extensive swelling.

Spasmodic dyspnea is most frequently found in connection with rickets, of which disease laryngismus stridulus is but a symptom, whose presence makes the diagnosis easy. Absence of fever and transitory character point to the affections being functional. The various reflex causes already mentioned should be sought out.

The causes of compression should be remembered. When present they are, as a rule, easily found. Abscesses may at first be difficult to discover. In some cases it is not easy to ascertain the seat of the obstruction, for bronchial dyspnea may closely simulate laryngeal or tracheal dyspnea. The laryngoscope, X-rays, auscultation and percussion may be necessary.

Treatment.—In dealing with laryngeal and tracheal obstruction there are four agents that must often be used—used with a skill that all should try to acquire, namely, the antitoxin syringe, the O'Dwyer tubes, the laryngeal forceps and the knife. Intubation, tracheotomy and, certainly the use of forceps for the extraction of foreign bodies and the removal of growths should be first practiced on the cadaver. Malformations, tumors and foreign bodies, while considered to belong to the domain of laryngology, often give rise to a dyspnea that brooks no delay, and with which the physician who is called in the urgency of the case must be prepared to deal.

Congenital glottic webs are divided by means of the laryngeal knife. The stridor due to the peculiar infantile shape of the epiglottis generally disappears at the third or fourth year.

Tumors are usually removed by evulsion or crushing, with the aid of the laryngoscope and local anesthesia. Tracheotomy may precede or accompany these measures. Laryngotomy is employed only as a last resort, but may be necessary in young infants where death from suffocation is imminent. Intubation may in some cases be employed for temporary relief.

Foreign bodies, if they can not be removed by means of the laryngeal forceps and mirror, may require tracheotomy, and usually do in infants; the high operation for bodies in the larynx and the low one for those in the primary bronchi. The administrations of emetics and the reversal of the patient's body, as formerly practiced are dangerous, for if the foreign body be in the trachea, it may become wedged in the glottis. Inflammations may render necessary scarification, intubation or tracheotomy. They are best treated by applications of ice from the beginning. Derivatives and antispasmodics may be required to check accompanying spasm. The best remedy is probably codein, of which one milligram may be given at a dose to a child one year old, or morphin one-third of a milligram. Congenital syphilis requires mercurial inunctions and the internal administration of syrup of iodid of iron. When in the course of any of the acute diseases mentioned, a progressive, urgent dyspnea, accompanied by anemia and asthenia arises, it is best, as before remarked, to administer antitoxin at once, for nearly all such cases will prove to be due to the presence of the Loeffler bacillus. Prompt use of the serum will arrest the stenosis and render intubation unnecessary. Often, however, that operation will be required, not only in membranous but also in edematous, spasmodic and cicatricial stenosis. The tubes can be retained for long periods, a week or more without injury, those of hard rubber are best for long retention. Tracheotomy is not often required. For the relief of aphthous stenosis, Massei considers the ordinary catheter the best instrument. It can be used often and for brief periods to relieve the stenosis and detach the masses of oidium albicans. This instrument is invaluable for any form of dyspnea where the O'Dwyer tubes are not at hand. Cicatricial stenosis may render necessary repeated dilatation, prolonged retention of tubes or tracheotomy.

Aside from the treatment of the predisposing systemic condition, spasmodic stenosis is relieved by chloroform, codein, chloral, bromids and other antispasmodics and by the removal of adenoids and other excitants. Intubation or catheterization will sometimes be indispensable.

Pressure stenoses are treated by removal of enlarged glands, evacuation of abscess. and sometimes intubation or tracheotomy.

PHARYNGEAL OBSTRUCTION.

In the pharyngeal region hypertrophied tonsils, peritonsillar abscesses, retropharyngeal abscesses, elongated uvulæ, cicatricial contraction and the presence of foreign bodies, are causes.

Hypertrophied tonsils, although often congenital, rarely gives much trouble before the second year. They cause snoring, imperfect articulation, dysphagia and offensive breath. Often concurrent adenoids add their symptoms. If the tonsils nearly meet they should be excised; if they project but slightly, they should be let alone. Peritonsillar abscesses should be opened just outside the upper edge of the tonsil. Foreign bodies are to be carefully sought for and removed. The epiglottis has been found fastened down by pins and fish-bones. Cicatricial stenosis from syphilis sometimes occurs in infancy. The soft palate may become adherent to the pharynx, so as to completely shut off the nasopharyngeal tract. Operation is not then very successful. Elongated uvulæ may cause reflex cough and need removal. The palatopharyngeal space may be so narrow as to impede respiration.

The one very important and often fatal obstruction met with in this region is retropharyngeal abscess from suppurating lymph nodes or vertebral caries. This disease belongs to infancy, three-fourths of the cases occurring in the first year. Influenza is perhaps the most frequent cause. Sometimes it follows scarlet fever. The symptoms are fever, prostration, dyspnea, pain, dysphagia, aphonia or dysphonia, the cry being of a peculiar guttural character. Inspiration is accompanied by a very characteristic snoring sound which attracts the attention of the examiner, to whom the fauces and pharynx appear normal where the abscess is low. The abscess, although bulging most frequently directly behind the mouth, may be hidden above the palate, latterly by the faucial pillars or below, opposite the larynx. In all cases of infantile dyspnea where the diagnosis is not clear, the pharynx should be explored with the finger. Called once to intubate a nearly suffocated child, considered by two physicians in charge to have laryngeal stenosis, the author found a large abscess at the level of the larynx. Incision gave prompt and permanent relief. These are often dangerous cases. Death has occurred from the slight increase of obstruction due to the insertion of a mouth gag preliminary to operation. If not found and evacuated, the abscess may kill by eroding large blood vessels or by bursting into the larynx. Starvation and dyspnea usually kill. In scrofulous children the abscess may refill many times. In such cases general hygienic treatment and the administration of small doses of calomel for long periods has given the best results.

The abscesses of Pott's disease are of rather rare occurrence and long duration. They surely refill. Occasionally they can be opened externally and should be.

NASAL OBSTRUCTION.

Passing now to the study of abnormal respiration from obstruction in the nasal and retronasal spaces, we find effects and symptoms of another order. Not from interference with the free entrance of air to the lungs does the patient suffer, but because of interference with the passage of air through organs designed for purifying; warming and moistening it preparatory to its reception by the delicate organs through which it is assimilated; for such is the function of the mucous membrance of the nasal chambers, whose superior half, moreover, depends upon the air current for the stimuli of the myriad olfactory impressions conveyed by its nerves and so necessary to mental development and the enjoyment of life. Just as the digestive organs prepare food for absorption do the nasal passages prepare air.

Since the free passage of air is necessary for maintaining an equal atmospheric pressure on both sides of the tympanic membrane, impeded nasal respiration must cause imperfect hearing.

Again, the nasal chambers and antra modify the phonatory vibrations that pass through them. Their obstruction therefore renders imperfect vocalization inevitable. Not only is mouth breathing present and audition, olfaction, articulation, respiration, and consequently growth and development of mind and body seriously impaired, but the lungs, ears and eyes are rendered prone to catarrhal inflammations. Anemia is almost constant.

The effects of nasal obstructions are now becoming generally recognized. No one now doubts that the early relief of this condition enables a stunted backward child to grow and develop marvelously, reaching a perfection impossible without it. Indeed, the recognition and treatment of this condition should be a national care, for it means higher racial development. All familiar with the extraordinary improvement in a child after the removal of adenoid growths, will readily admit this. The peculiar physiognomy of some backward races, the Esquimaux for instance, is believed to be due to the presence of these last-named growths during childhood.

Causes.—Apart from malformations, the most important of which are absence of the septum and floor of the nose, which render respiration abnormal, and imperforate or extremely narrow nostrils, any of the following causes of obstruction may be congenital: Complete or partial occlusion from exostosis, ecchondrosis and deviations of the septum, hypertrophy of the turbinated bodies, bony cysts of the middle turbinated, polyps, abscesses of the septum. Frequent causes are, foreign bodies, fractures, diphtheritic membranes, syphilitic lesions and what is not at all rare, and yet has received little or no mention so far as the author knows, in the literature of the subject, collapse of the alæ nasi.

The acute inflammations are but transient.

In the nasopharynx is found by far the most frequent and important cause of nasal obstruction in infants, the so-called adenoid growths. Although often present in the new-born, it is toward the end of the first year that they are generally found. They are idiopathic or the result of acute infectious inflammations, especially influenza, a disease which few children escape during its prevalence.

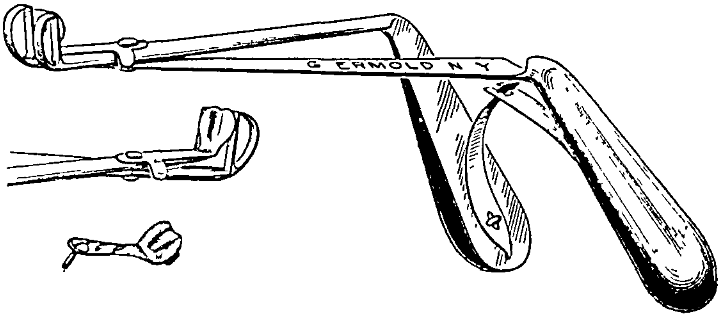
Symptoms.—An infant having nasal obstruction from any cause presents an expressionless face, with open mouth and flabby folds, stretching down from the alæ of the generally flattened and running nose. This has been called the veiled face of adenoids. Deafness, otitis, mutism, anemia and eye affections are often present. The voice has a dead, nasal character, that of cold in the head. Snoring, restlessness, night terrors, inability to nurse are always present in cases of large growths. Postnasal, laryngeal, bronchial, aural and conjunctival catarrh are frequent accompaniments. Not only is nasal obstruction often the reflex of very distant irritants, but it may be the cause of apparently widely separated affections, such an enuresis. Fits of crying and continued frowning indicate headache. The mouth-breathing infant is generally anemic, puny, ill-developed and frequently affected by diathetic diseases. The rachitic are frequently mouth breathers; while predisposing to other diseases, the presence of nasal obstruction causes infants ill from any cause to do badly. An interesting case was recently reported in the *New York Medical Journal* of a child which having complete nasal obstruction from birth, with inability to nurse, died when one week old. At the autopsy the turbinated bodies were found congested to such an extent as to cause complete occlusion. Surgical treatment had not been attempted.

Diagnosis.—The first diagnostic procedure should be an examination of the nasopharynx; for adenoid growth will be found in four-fifths of the infants with chronic nasal obstruction. In a few seconds the physician's index or little finger slipped behind the palate, over the vomer and down the posterior pharyngeal surface, will not only have met the soft, pendant, easily bleeding masses, blocking the posterior nares, but will be found blood stained when withdrawn. In infants under six months, such examination being impossible, an applicator armed with a cotton nob introduced behind the palate or through the nose, touching the masses ever so gently, causes them to bleed, showing their presence. Anterior rhinoscopy requires some practice before a reliable diagnosis can be made of the obstructions in the nasal chambers. A novice in rhinology is most likely to fail in even so simple a matter as distinguishing a red fleshy hypertrophy of the inferior turbinated body from the gray oyster-like polyp of the middle turbinated. Nor can he easily determine whether it be a growth or a deflection that affects the septum.

Intranasal obstructions are, however, comparatively rare in infants. Abscesses of the septum have been found five times in the author's practice. It is easily recognized by the bilateral bulging of the septum. The probe detects bony or cartilaginous growths that completely or partly occlude. Collapse of alæ should always be thought of before a speculum is introduced. Unilateral occlusion with purulent discharge often means the presence of a foreign body, such as a shoe button or grain of corn. In diphtheria the anterior nares are usually excoriated and covered with a gray pellicle. The Loeffler bacillus is always present. The membranes may be confined to the posterior part of the nose and retronasal space.

Treatment.—Apart from the finding and removal of the reflex and other causes, when general treatment fails, hypertrophy of the turbinated bodies are reduced by the galvanocautery or snare; exostosis and ecchondroses are drilled through with the electric trephine. Bone cysts and polyps are snared away, abscesses opened and foreign bodies removed by means of forceps or hooks. Syphilitic lesions require mercurial inunctions and thorough cleansing. Nasal diphtheria demands prompt injection with antitoxin, in large doses and repeated until the membranes cease to recur. This form of the disease indicates not only its virulence, but that the patient is non-resistant. When collapse of the alæ exists it is treated by means of springs or frames that maintain the form and size of the nostril.

Practically, however, the treatment of nasal obstruction in infants means removal of retronasal adenoid growths. The operation requires but a few seconds of time and no anesthetic. Cutting forceps and Gottstein curettes are employed. For growths on the posterior wall of the retronasal space the latter is the best. The forceps better reach the high growths which hang into the posterior nares and cause most of the obstruction. To prevent the injuries to the vomer, uvula and Eustachian tubes, which often occur with inexpert operators, and to guide the instrument into proper position for effective work, the author has devised a plate of peculiar shape which fits over the open jaws of the forceps and, when introduced, over the posterior edge of the vomer, also enables the operator to bring all the growths within the blades. This instrument accomplishes the operation at one application. Only when there are extensive posterior growths a single sweep of the curette may supplement the forceps. The latter instrument has the advantage that the growths are always brought away with it, while with the curette they are usually swallowed.



Hemorrhage nearly always ceases in a few moments. Three fatal cases have been reported. To check it, pledgets of cotton, saturated with solution of acetate of aluminum, should be drawn up into the nasopharynx by means of cords passed through the nose, and tied over the columna. Salt water irrigation, thrice daily for two or three days, is the only after treatment. Over two hundred cases have been treated in this way in dispensary practice with no evil effects whatever. The operation is invariably successful.

Rachitis, rhinitis, chorea, reflex cough, eye troubles, deafness, malnutrition, laryngismus, laryngitis, enuresis, night terrors and aprosexia will often resist the most careful treatment until the accompanying adenoids are removed, when convalescence will be rapidly established.

Having thus briefly dealt with the important subject of dyspnea in children under three years of age, it may be permissible to emphasize: The importance of laryngology in pediatrics; the facility with which the larynx may be examined even in infants; the necessity for ascertaining the condition of the upper air passages in all children, and for the removal of obstructive adenoid growths; the many causes of nasal and laryngeal dyspnea in infants, amongst which drawing in of the nasal alæ, sprue, inhaled irritants and foreign bodies are often overlooked; *the frequency of* retropharyngal abscesses, necessitating digital exploration of the pharynx; that the bacillus of Loeffler is often the cause of laryngeal stenosis in acute diseases, and demands prompt use of antitoxin; that these helpless little beings, who can not, often will not, give a history, should receive the benefit of all modern methods in diagnosis that they may enjoy normal respiration.

PUERPERAL INFECTION.

Presented to the Section on Obstetrics and Diseases of Women, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, June 1-4, 1897.

BY J. E. COWLES, M.D.
LOS ANGELES, CAL.

As this does not pretend to be an exhaustive treatise on puerperal fever, so-called, I will make no apology for slighting certain parts of the subject; and if I seem to wander too near the boundary line of the undiscovered, it will not be for the sake of the theorizing, but with the desire to draw, from reasonable inferences, certain conclusions that may assist in our every-day work. In regard to a choice of name for the puerperal condition now under consideration, there is not entire unanimity among medical men. Garrigues objects to the term puerperal fever, principally on the ground of its expressing only a symptom and in exceptional cases not even that, as he states there is sometimes no fever at all. Metria, he thinks too vague, and septicemia too strong a term for mild cases; therefore, he prefers the term "puerperal infection" and while admitting that it refers more particularly to etiology, he thinks it may also stand for the pathologic process, just as "cold" is used by the laity and profession also for both conditions. He claims for it the great advantage of pointing out that the disease comes from without, thus impressing on us the necessity of taking measures to prevent it. Puerperal infection, then, being the most available term in the present state of our knowledge, may be used as a general term, and the words septicemia, pyemia, etc., may stand for peculiar and grave states of this infected condition. The time-honored name, puerperal fever, may be retained also for association's sake, even if we can not find any rational basis on which to rest its claims, looked at from the standpoint of a purely scientific classification. As to the identity of the causes of surgical and puerperal infections, about which there has been so much discussion in times past, I believe the consensus of medical opinion of today is on the affirmative side of the question. In view of the accumulated experience of the most enlightened physicians of the last two decades, aided by the revelations of the microscope and the results of bacteriologic research, all tending to establish beyond the peradventure of a doubt, the identity so far as cause is concerned, of the two conditions, it should be hard indeed to find an advocate of the dual theory. The idea of identity, as I understand it, is not that the two conditions are dependent on a particular kind of germ, the poison *sui generis* of Barker, but that they are both dependent on the presence of germs, be they all of one kind (if it were possible), or of many kinds, and that there may be as much similarity, or, if you please, identity, between a given case of puerperal infection and surgical infection as there would be between two cases of surgical infection all the time allowing for the greatly differing conditions of the two cases. For, as Lusk expresses it: "In the puerperal state it is necessary to take into account the blood changes induced by pregnancy, the effects of shock and exhaustion in protracted labor, the frequency of hemorrhage, the deep situation of puerperal wounds, the presence of clots, decidua and dead tissues in a state of disintegration or decomposition, the ease with which deleterious substances are absorbed by the wide lymphatic interspaces, the serous infiltration of the pelvic tissues, the exaggerated size of the lymphatics and veins, and the proximity of the peritoneal cavity;" and, therefore, he concludes "that the differences between surgical and puerperal septicemia are due to differences partly structural and partly physiologic in the wounded surfaces exposed to septic contamination, but that the two conditions are not only analogous but essentially one and the same process."

That the puerpera is much more liable to infection than any surgical case will hardly be denied, for "it is a fact independent of all theories."

Blood clots and decidual shreds most certainly furnish good material for infection, but from experiments made by Prudden, a detailed account of which was given in the New York *Medical Record* of Jan. 25, 1890, he conclusively shows that, whereas, all the other body fluids have more or less germicidal effect, amniotic fluid, on the contrary, proved to be such a good culture-medium that typhoid bacilli planted therein almost quadrupled their number in six hours after implantation.

Etiology.—The query as to what is puerperal fever is answered by a practical obstetrician as follows: "It is a disease due to a poison coming from without, the cause of which seems to be produced by certain microbes. That the severe cases are due to septic organisms is proved by the fact, that by antiseptic measures we succeed in preventing the disease and if it has made its appearance they have great power in conquering it. Another proof is, that microbes have been found in such numbers and under such conditions that they must be regarded as intimately connected with the disease—but this properly belongs to the bacteriologist."

That scientist adds: "Emphatically, yes. Bacteria *are* connected with this disease as causal factors." When asked for his reasons for such a statement he reminds us that, following Tyndall, a number of investigators have proven beyond a doubt "that bacteria do not arise by spontaneous generation anywhere," thus establishing the law *omnis cellula e cellula*, the only law, so far as I know, without an exception. "This being true, as well as the fact that bacteria have never been found in the body in a state of health their presence there in disease must be ascribed to an entrance from without and the finding of suitable conditions for their development after this entrance has been effected. Therefore we can confidently affirm that bacteria or their products are the exciting causes of such affections as the pyemias and septicemias."

Pasteur and Doleris give as results of their work, four varieties of bacteria occurring in cases of puerperal infection, which they classify as follows: 1. Cylindric bacteria or bacilli, developing into large filaments about the time of the death of the patient and called *bacteries septiques.* and commonly found in malignant septicemia. 2. Mi [illegible] in [illegible] ns, called streptococci. 3. Diploco [illegible] ring in pyemia, as the micr [illegible] Micrococci *occurring singly* [illegible] From the nature of the subj surrounding it, it is impossible at this stage of investigation, to associate any one or several of the different species of micro-organisms, as causing a definite array of symptoms in any given case of septic trouble, except to say in a general way that the most serious infections are due to the bacilli and streptococci. "If we have chills and a rise of temperature to 40 degrees C., we may assume, almost with certainty, the presence of the streptococcus." So far, the following bacteria have been found in causative relation to, or thought capable of causing puerperal fevers, viz:—The streptococcus pyogenes of Passet; the streptococcus erysipelatis of Fehleisen; the streptococcus septicus of Nicolairer; the staphylococcus pyogenes aureus of Rosenbach; the staphylococcus pyogenes albus; the staphylococcus pyogenes citreus of Passet; the staphylococcus pyogenes circus albus of Passet; the bacillus coli communis of Escherich; the bacillus saprogenes of Rosenbach; the bacilli of rabbits and mice septicemia; the bacillus pyogenes fetidus of Passet; Noeggerath's saprocyte and others.

As to the modes of entrance of these poisons into the system, unquestionably the vast majority of cases are infected through a solution of continuity, at some point or points within the genital tract, but there are a few cases on record that can only be reasonably explained upon the supposition that the germs gained admission through the respiratory or digestive tracts; but the percentage of these cases is so small as hardly to merit consideration.

Pathology.—As infection may cause a septic vulvitis, vaginitis, endometritis, salpingitis, ovaritis, peritonitis, lymphangitis, phlebitis, pleuritis, pneumonitis, etc., so will be added the special pathology of one or more of these inflammations, as they exist, plus the peculiar pathology of the particular bacteria present, such as pus, diphtheritic membranes, etc. It is thought that, where the round bacteria exist in great quantities, you are apt to find emboli and infarctions, ending in metastatic abscesses characteristic of pyemia and so frequently found in the liver, kidneys, spleen, parotid gland and other glands; or, if the more virulent bacilli predominate, we are told that the only pathologic change, sometimes observed, is a very coagulable blood and at other times an excessively fluid state of the blood, each condition supposedly due to the chemic action of the animal alkaloids produced by the germs.

Mortality and prognosis.—We are all familiar with Max Boehr's statistics and the report of the Berlin Society, and since we gather from them that before the period of antiseptic midwifery 10 to 15 per cent. of all deaths occurring in women, during the period of sexual activity, was due to childbed fever" and that at a later period with imperfect antisepsis this appalling mortality was reduced to 4 per cent. at the New York Maternity Hospital and later to a quarter of 1 per cent. with a more perfect system, we can praise the Lord that he put it into the minds of men to study this much neglected subject.

In addition to this great saving of life antiseptic midwifery, as Garrigues tells us, has reduced morbidity from 25 to 3 or 4 per cent. The prognosis of puerperal infection depends upon the *character* and amount of poison absorbed in the particular case under consideration, together with the character of the tissues or organs involved. As a material help to prognosis and treatment, a microscopic examination of some of the cervical discharge should be made by a competent microscopist.

The symptoms of puerperal infection may be as varied as its pathology. They may vary from a slight headache, anorexia and mild fever for a few days, the so-called milk fever, to a case with severe and prolonged chill or recurring chills, rapid pulse, high temperature, sweet breath, dusky or jaundiced skin and anxious face of acute septicemia, soon terminating in collapse and death. The local inflammation, as a peritonitis, may impress its symptoms in a given case. Again, we may have an array of symptoms characteristic of pyemia, with such sudden rises of temperature followed by profuse sweating and marked remissions of temperature, as often to be confounded with malaria. If it is true that micro-organisms have the power of producing animal alkaloids, with properties as varied and with effects as marked as are characteristics of those vegetable alkaloids with which we are familiar, such as atropia, aconitia, etc., then it should not appear strange, if we should note symptoms in certain cases similar to those produced by large or toxic doses of these powerful medicines. Bearing this possibility in mind, we should be on the alert for symptoms caused by these little understood but none the less real and potent substances. In case of a sudden collapse and death (and who of us have not heard of such during supposed puerperal convalescence, with a death certificate given of "heart failure") due, perhaps, to the leucomain analogous to aconitia, secreted within the individual herself where we were giving aconite in large doses, to know of the possible presence of this leucomain, might save us from unmerited reproach and qualms of conscience.

Prophylaxis.—By far the most important consideration during the lying-in period is to obtain as conscientiously perfect asepsis as is possible and no amount of trouble either to the accoucheur or attendants should be declined to secure this *sine qua non* to the puerpera. "For here if anywhere, a man is weighted with responsibilities of a momentous nature, even such as he is called upon to sustain in no other social, professional or individual capacity." I maintain that considerations of delicacy or false modesty as in the past, should not be allowed such paramount importance, as to prevent such a careful aseptic toilet of vagina, vulva and contiguous parts as an up-to-date surgeon would order given as a preliminary to a vaginal hysterectomy.

If the obstetrician is not sure that the nurse knows how to scrub out and disinfect a vagina thoroughly, he should do it himself, after all hair has been removed from around the vulva, and order antiseptic pads changed *pro re nata* or frequently, both before and after the completion of labor.

A word of explanation as to the necessity and importance of this cleansing should be impressed on the puerpera herself, and a caution as to keeping her hands away from the cleansed parts should not be overlooked, as every observant accoucheur can testify. The writer rigidly adheres to Garrigues' rules "for and in such cases provided" and he thinks he has cause for gratulation and gratitude, as in from 1,200 to 1,500 cases attended by him, he has had no death from puerperal fever and but few cases of morbidity. In 18[illegible]0, writing on this subject, I used the following language: "While I do not use the intra-uterine douche as a routine measure, I know of no good reason why it should not be done, and if, as seems certain, liquor amnii is such a good culture-fluid for bacteria, it would seem but in the line of common prudence to wash it away and by the same process and at the same time, get rid of placental shreds and blood clots, generally recognized as sources of danger. Besides, the hot uterine douche assures good uterine contraction, and I believe it is but a question of time, until this excellent prophylactic measure will be advocated ex cathedra, as correct practice after every delivery, at least where there is no trouble about having satisfactory antiseptic arrangements. Until then, I shall consider the surgeons a step in advance of the obstetricians."

I notice that Alexander Duke, of Cheltenham, England, writing to the *Medical Press and Circular* of London, in September 1895, states that he thinks "that an antiseptic treatment in midwifery would be seldom required, if the aseptic were more attended to, one of the most important plans being thorough flushing of the *entire genital tract* directly after labor. Those who have not taken the trouble on themselves to thoroughly wash out the uterine cavity directly after labor, the time when it can be best and easiest accomplished, can have little idea of the amount of débris which, if left behind, must take a considerable time to be expelled and is certainly likely, to say the least, to prove a source of danger to the lying-in patient."

A prophylactic caution that should be observed in every case, is to examine rarely and not to introduce the finger within the os in ordinary cases. When it is absolutely necessary, follow it with an antiseptic douche, also express placenta by Credé's method. Squibb's fluid extract of ergot in half teaspoonful doses, or one-thirtieth grain of strychnia, three times a day for five or six days, as well as immediate suturing of any laceration worthy the name, is important prophylactic treatment.

I shall make no apology for thus having dwelt at length on the most important part of this very important subject. I must say in passing, that I have had great comfort in postpartum douching of the uterus, in using a thick-walled, properly curved, glass tube, nine or ten inches long and as large as the thumb, which I think could be improved by deeply fenestrating the outer curve at its distal end for four or five inches.

Treatment.—If proper attention has been paid to prophylaxis, there will seldom arise a necessity for other treatment, but I believe that once in a great while one will run across a case of autogenetic infection from a ruptured pus tube or abscess sac, ovarian dermoid or other abnormality within the pelvis. In such cases evidently celiotomy with careful toilet of the peritoneum and drainage would be the remedy. In case the genital tract has been infected, I am an earnest advocate of early and very careful curettage and swabbing the uterine cavity with iodized phenol, without irrigation, but insufflating boric acid and packing lightly with iodoform or acetanilid gauze; or, what I sometimes like better, sew into the cervix a perforated one-fourth of an inch glass tube and fill the vagina with iodoform gauze. If, in spite of this treatment, faithfully tried, general infection ensues, it would certainly be proper to inject hypodermically the antitoxin serum appropriate for the preponderating germ present.

The most modern treatment of general septicemia is that of hypodermic injections of creosote recommended by Frank of Cologne. Its administration is said to be attended with remarkable results, rapidly reducing the temperature from 104 degrees F. to normal.

The solution that I have used in 20 minim doses, three or four times in the twenty-four hours, consists of equal parts of pure beech-wood creosote and sterilized camphorated oil. It is a beautiful, light amber colored liquid with only a slight smell of creosote and its injection does not seem to be attended with any disturbance or reaction. Failing in this special treatment, coupled with strongly supportive and stimulating general remedies, if the uterus and adnexa are thought to be a hotbed of infection, one would be derelict in his duty, if he did not give the patient her last chance by removing them; and I would most earnestly urge the vaginal method where possible, as causing less shock and securing better drainage.

ANTI-STREPTOCOCCUS SERUM.

BY C. P. THOMAS, M.D.

SPOKANE, WASH.

During the last four months we have used this new remedy eight times, and notwithstanding that the cases treated were of very severe nature, the results have been so universally good that I feel it a duty I owe to the profession to report them.

I will be unable to give a correct clinical report of the cases, for no notes were kept, but they are sufficiently recent I hope to make them plain to you from the mental picture which I still have.

Mrs. A. was being treated by Dr. Button for acute cellulitis of the arm following an infection of a slight wound on the finger. She came to him after having been treated indifferently for two weeks, with a much swollen arm considerably distended with pus. Her temperature at this time was not very high. Under strict asepsis, free incisions were made into the arm, much pus evacuated, and the arm enveloped in a moist bichlorid dressing. Three days later, a violent erysipelatous condition came on, the temperature rose to 104 degrees, the patient suffering great pain; she was almost pulseless and death seemed imminent. She was given 10 c.c. of Marmorek's anti-streptococcus serum and also the usual stimulating treatment; and on his return twelve hours later, the Doctor found the temperature to be 100 degrees, and she continued to improve until complete recovery took place.

Mr. B., who was under the care of Dr. Byrne, came into the hospital the second or third day of the disease with acute erysipelas involving one entire leg; place of inoculation, a small varicose ulcer. The entire leg was swollen and from the knee down the limb was almost black with edema. His temperature was 106 degrees and he was unconscious. He was given 10 c.c. of the serum in the evening, and next morning his temperature was nearly normal, tongue moist, the swelling subsiding, and he went on to a rapid recovery.

The third case was also under the care of Dr. Button, and was one of acute suppurating appendicitis, in which we flooded the general peritoneal cavity with pus during the operation by the breaking of a very thin wall of protective membrane. Twelve hours later the patient showed great restlessness and other symptoms, well known to abdominal operators, of beginning peritonitis. He was given the usual dose of the serum and all these unpleasant symptoms disappeared and he made a rapid recovery.

The fourth case was a boy of 14 years of age, with acute obstruction of the bowels, who had recently been operated on for an abscess of some sort in the region of the vermiform appendix. He came under my care forty-eight hours after the attack began, with a high temperature, greatly distended abdomen and every indication of acute peritonitis. The abdomen was opened in a line with the old scar, which was parallel with Poupart's ligament and about an inch above it, adhesions broken up throughout the intestines, mesentery and omentum, the appendix removed, an operation done for the cure of the incisional hernia, which was very marked and the wound closed without drainage. All parts of the abdominal viscera showed marked evidence of acute inflammation. He was given the serum injection at once and recovered.

The fifth was a case of erysipelas beginning in an axillary abscess which involved the skin and muscles of one entire side of the chest. He was also greatly prostrated and suffering from a very high temperature; one injection of the serum was given him, with the same results as the others.

The sixth was a case of ruptured pus-tube of probable specific origin, which also had the usual high temperature, tympanites and great prostration. She was operated on through the vagina, the leaking tube removed and the general cavity thoroughly drained with rubber tubes and gauze. She was given at the time of the operation, the usual dose of serum, and although she was greatly improved, the next day it was repeated and her recovery has also been uneventful.

The seventh was a case of a large leaking pelvic abscess. The patient was in worse condition than any of the others, the bowels greatly distended, and very tender on pressure; she was vomiting persistently and there had been no passage for three days. Up to this time, she had been under the care of a colleague and given the opium and saline treatment. She was given the serum and immediately opened through the posterior fornix and about a pint of foul smelling pus evacuated from the abscess cavity. Both it and the general peritoneal cavity were thoroughly irrigated and drained. At the end of twelve hours her bowels moved with but little effort, the vomiting gradually subsided, and she is now almost recovered.

The eighth was a case of acute sepsis coming on about nine days after a very difficult labor, in which she was severely lacerated. She was irrigated and curetted two or three times before being sent in from the country, but her temperature remained high and there was some distention of the abdomen. She was given the serum treatment after the temperature had remained up for four days, all intra-uterine treatment stopped and, within twelve hours, the temperature became almost normal and remained so for ten days, when she was again suddenly taken with a chill and very high temperature, which resisted all constitutional treatment for three days, when she was again given 10 c.c. of the serum. The next day it was found that her temperature was not so high and there was some bogginess in the posterior fornix. The serum was repeated, the fornix opened and drained of a small accumulation of serum, and the uterus again thoroughly curetted, considerable placental tissue being removed. The following day she still had a very high temperature, showed evidence of the most profound toxemia and the serum was again given, and from this time on she continued to improve, the temperature remaining normal after the eighth day. This case would doubtless have been subjected to a hysterectomy by some of our advanced surgeons, but I consider her in a much better condition than if she had lost her uterus.

While it is true that some of the above reported cases might have recovered without the serum, considering the fact that so eminent an operator as Dr. Nicholas Senn has just admitted that out of over fifty operations for general peritonitis which he has done, not one has recovered, it appears to me that much credit must be given the serum in these cases. This represents my entire experience with the serum and I have used only that which was prepared by the Pasteur Institute and obtained from their branch house in Chicago, the Pasteur Vaccine Co. It comes in single bottles of 10 c.c. each, and is given with the antitoxin or ordinary hypodermic syringe.

URTICARIA, A THERAPEUTIC NOTE.

BY BERNARD WOLFF, M.D.

ATLANTA, GA.

The list of remedies suggested for the relief of urticaria is already so voluminous that I would have some hesitation in further adding to it, were I not thoroughly convinced of the value of phosphate of soda in the treatment of this common complaint.

I have used this drug for the past year in quite a large number of cases, and with such uniform success that I have come to regard it as absolute master of the disease, and have ceased to have any of my former misgivings of my ability to promptly relieve the patient.

In acute cases in adults my plan is to give dram doses of a supersaturated solution of phosphate of soda, *i. e.*, sixty to eighty grains to the dram, the salt being dissolved in its own water of crystallization. This is to be repeated every three hours, and in addition the following antipruritic lotion is recommended:

℞	Pulvis Calamin		
	Zinc. Oxid.	āā ʒiss	6
	Acid. Carbolic	ʒ ss	2
	Aq. Calcis	℥ ij	64
	Aq. Rosæ	ad ℥ iv	128

This is to be applied frequently and freely. The dose of the salt may be appropriately reduced in the case of children, and the quantity of carbolic acid in the lotion diminished. The effect is prompt, within a few hours the acute symptoms subside, and in from twelve to twenty-four hours the eruption ceases to appear.

In the chronic type of the disease the relief afforded is equally prompt, but recurrences are apt to follow. The remedy should be given in doses of one dram or more after meals, and should be persisted in until all tendency to recurrence of the attacks has disappeared. Patients do not acquire a tolerance for the drug and therefore, it may be administered in unchanging doses for as long as is necessary without any injurious effect.

The remedy is especially applicable in urticaria of gastro-intestinal origin, and is consequently applicable to fully 90 per cent. of all cases.

Sodium phosphate is regarded as one of the most reliable hepatic stimulants and intestinal antiseptics, and its curative influence over urticaria is probably based upon this physiologic action.

The Paris Hospitals.—It is stated by the correspondent of the *Medical Press and Circular* that the hospitals of Paris need the expenditure at least of one million pounds to make them habitable, and a further outlay of another million to make them what they really ought to be.

ACNE ROSACEA TREATED BY INTRADERMAL INJECTIONS OF FORMALDEHYDE.

BY J. T. McSHANE, M.D.
INDIANAPOLIS, IND.

The patient, an unmarried lady 30 years of age, has suffered from acne rosacea, with pustulation and papulation for about ten years. The entire face was involved with redness, most marked over cheeks and nose, and always worse during menstruation. The patient is well nourished but has suffered from nervousness and [illegible], perhaps due largely to her necessary [illegible] society on account of the bad appearance of her face. She has been under the professional care of several first-class physicians and all the usual means of treatment have been resorted to, but without avail.

I decided with the consent of my patient to use intradermal injections of formaldehyde in the strength of 1 drop of the 40 per cent. solution to 100 drops of water. These injections are attended with a stinging pain which the patient compares to the sting of a bee. One-half to one minim was injected in each point selected, care being taken to pass the needle into but not under the skin. In a few moments a spot about the size of a 10-cent piece, immediately surrounding the point, presents an elevated surface resembling urticaria. A sufficient number of injections were made at each treatment to thus affect the whole area of the disease and the treatments repeated at intervals of one week. The results have been most gratifying, and now, after three months' observation and treatment, the face is normally white with little or no tendency to recurrence of the disease.

26 East Ohio Street.

OVARIAN CYST.

Presented to the Section on Obstetrics and Diseases of Women at the Forty-eighth Annual Meeting of the American Medical Association, at Philadelphia, Pa., June 1-4, 1897.

BY A. M. CARTLEDGE, M.D.
LOUISVILLE, KY.

I desire to report a rather unique case. The woman from whom this cyst was removed was 37 years of age and lived in a hovel a great distance in the country. I saw her May 13 and operated the same day. The tumor had been growing for thirteen years, and for the last four years very rapidly, so that she was unable to assume the reclining posture for more than a year and a half. The circumference at the umbilicus was seventy-nine inches. The woman was five feet four inches in height and well formed, except that she was very much emaciated from carrying this enormous cyst. Twenty-four gallons of ovarian fluid were removed before she was placed in position to be anesthetized. After that she was placed on her back and ten additional gallons of fluid withdrawn. The adhesions to the anterior parietal wall were terrific. Many ligatures were used and the operation consumed about two hours under unfavorable circumstances. The woman survived the operation fairly well, leaving the table with a pulse of 114. On the fifth day she had a normal temperature and a pulse of 108. Beginning with the sixth day symptoms of intestinal obstruction developed and she finally died. The fluid withdrawn weighed 240 pounds and the sac 5 pounds.

LENSES FOR THE STUDY OF THE SCISSOR MOVEMENT, CONIC CORNEA AND SPHERIC ABERRATION WITH THE RETINOSCOPE.

BY JAMES THORINGTON, M.D.
Adjunct Professor of Diseases of the Eye in the Philadelphia Polyclinic and College for Graduates in Medicine, etc.
PHILADELPHIA, PA.

As the scissor movement, conic cornea and spheric aberration, as recognized by the retinoscope, are so difficult of demonstration, except in the individual patient, the writer has had made three lenses which will illustrate these conditions respectively, when placed in front of his schematic eye; and thus the beginner in retinoscopy may have the opportunity to see, know and study these important and interesting manifestations, before proceeding direct and in comparative ignorance to his patient.

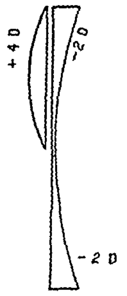

Fig. 1

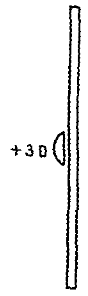

Fig. 2

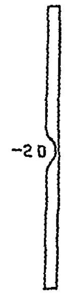

Fig. 3

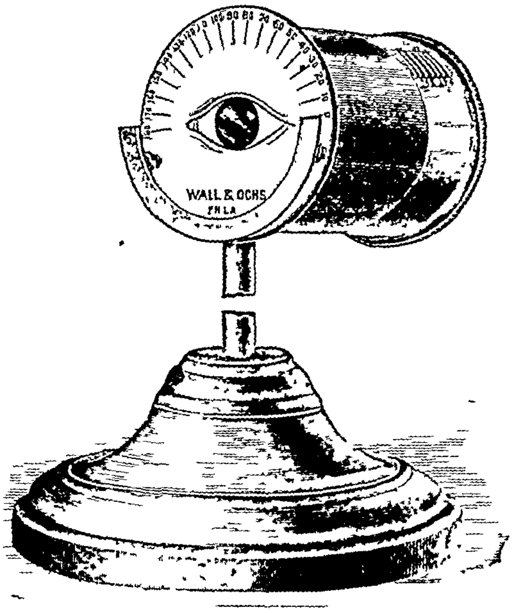
Figure 1, is a plano-concave cylinder of 2 D., mounted in a cell of the trial case and to one half of its plane surface is cemented (at the same axis) a plano-convex cylinder of 4. D., thus making a combination lens, one-half of which is a —2 D., and the other half a +2 D. Placing this lens with its axis at 180 degrees, before the schematic eye at emmetropia (zero) and the observer at one meter distance with his plane retinoscope, the two light areas, so characteristic of the scissor movement, with their straight edges and dark interspace may be seen approaching each other from above and below (and the dark interspace disappearing) as the [illegible] or i[illegible]d in the vertical meridian.



Thorington's Schematic Eye.

Figure 2 is a section of thin

as in figure 1, and has cemented at its center a small plano-convex sphere of 3 D., whose base is about 4 mm. in diameter. Placing this lens in front of the schematic eye at emmetropia (zero) and reflecting the light from the plane mirror at one meter, there will will be seen in the pupillary area a small central illumination which moves against or opposite to the movement of the mirror, and a peripheral ring (at edge of the iris) which moves rapidly with the movement of the mirror; between these two light areas is a dark ring. This is the retinoscopic picture and movement of the light areas, so indicative of conic cornea. It is also an exaggerated picture of negative aberration.

Figure 3, is made similar to figure 2, except at its center is ground a —2 D. sphere of about 4 mm. in diameter.

Placing this lens in front of the schematic eye at emmetropia and the observer seated as before and with the plane mirror, he sees in the pupillary area a central illumination which moves *slower* than the peripheral area (at the edge of the iris) which moves rapidly, both areas moving *with* the movement of the mirror.

After the observer has carefully studied these pictures, it will be obvious that changes other than those mentioned, can be made with these lenses and he should proceed to note them, by: 1, changing the focus of the schematic eye; 2, by placing both the convex and concave spheres in combination; 3, by varying his distance from the eye; 4, by placing a concave cylinder in front of the double cylinder at an oblique axis, thus getting the picture of compound irregular astigmatism; 5, by placing a concave cylinder of 1 D., in front of the convex sphere and developing astigmatism with the conic cornea, which is the usual condition. It is also obvious that the scissor movement can be produced by a prism which is made to cover one-half of the pupillary area, but the resulting picture is not as satisfactory for demonstration as that given by the combination lens referred to in figure 1. The instrument is manufactured by Messrs. Wall & Ochs of Philadelphia.

SURGERY ONE HUNDRED YEARS AGO.

AN HISTORICAL STUDY

BY DR. GEORGE FISCHER.

DEDICATED TO THE GERMAN SURGICAL ASSOCIATION.

TRANSLATED FOR THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION BY CARL H. VON KLEIN, A.M., M.D.

XVIII.—DISEASES OF THE THROAT, CHEST AND ABDOMEN.

(Continued from page 1219.)

Abscess of the liver required surgical treatment when it presented a fluctuating swelling on the outside. It could make its way through the diaphragm and appear outside on the thorax (Petit, Morand) or break through into the lung (Fourcroy), the intestine (Bajon) and stomach, and then heal. Generally it appeared on the lower short ribs, but seldom between the abdominal muscles and the iliac bone, in the right hand groin region, above on the inner side of the thigh (Bajon), where the diagnosis was very difficult. Also a well filled gall bladder was delusive and could be mistaken for an abscess in the liver. This was often and successfully opened: the sooner it was done the more certain was the cure, for there was no dependence on a spontaneous breaking of the same on the outside. Later the pus could separate the adhesions between the liver and the peritoneum and flow into the abdominal cavity. The abscess was opened with a rather large lancet, not by cauterizing, which would be apt to make the aperture too large. Schwartze had to pierce two inches deep before he reached the pus. When this smelled foul, camomile tea and honey were cautiously injected. A fistula might remain or death ensue from consumption. *Opening the gall bladder* was taken into consideration in fistulas and great accumulations. To effect a cure of the fistula it was usually necessary to extract the gallstones which caused the same, but only if the patient suffered excruciating pain. By means of catgut or a chisel the opening was enlarged until it admitted the finger, on which the forceps was introduced for the extraction. In this wise Zacharias Vogel of Lübeck had performed "one of the very finest of operations." In swellings of the gall bladder, which attained such a size sometimes that they were mistaken for encysted dropsy, an attempt to force the bile into the duodenum by gentle rubbing was made upon the presence of inflammatory symptoms. If it failed, the bladder was opened with the trocar according to Petit's mode of procedure, a very harmless interference as, on account of the inflammation, adhesion was assured and the tube was allowed to remain for a few days. Without a simultaneous inflammation it was not permissible to open the gall bladder, for fear of the probable adhesion with the abdominal wall. In order to produce the inflammation the peritoneum was exposed, spread with caustic, and after a few days the bladder was pierced.

A partial *extirpation of the spleen* was achieved by Ferguson. For twenty-four hours the spleen protruded from a wound and a portion of it was gangrenous. Around this piece, weighing three and one-half ounces, a piece of twine was placed; then it was cut off and a large, violently bleeding artery was tied. The remaining portion of the spleen was replaced, the threads hanging out of the wound wore off after ten days and the patient was soon cured.

We will now speak of *hernias*, in the study of which a lively interest was manifested. Their history is especially glorified by the names of J. L. Petit, Arnaud, Garengeot, Morand, Pott, Guenz and Richter. The latter arranged the scattered material in his classical book in such a brilliant manner that his work was the authority on the above subject until A. Cooper's time. As early as the beginning of the century, attempts were made to scientifically explain the mechanism of the formation of ruptures, and to end the strife whether the nature of hernia was due to displacement of the peritoneum or to rupture of the same. The latter idea was the more prevalent one. German surgeons manifested but little interest in these researches. Heister did not know for which opinion to decide, compared the different views expressed, and produced authorities for the one and the other. Wideman (1719), a lithotomist and cataract curer in Augsburg, expressed himself more clearly and earlier than Heister, saying that "in reality no tear exists, only a distention, discharge and obstruction are found." The first scientific attempts were made by Reneaulme ("Essai d'un traité des hernies." Latin edition, 1721; French, 1762), who looked upon the rupture portals as fissures, from which the outer membrane of the peritoneum along the vessels, which protrude from the abdomen, continues as a divide; the peritoneum is always well and unimpaired, if not maltreated in some peculiar way. His theory was more fully executed in detail by Garengeot (1732), whose writings enjoyed a great circulation. But he as well as Arnaud had experienced, that after a violent thrust or great exertions the peritoneum burst and thus a rupture ensued without a hernial bag. Soon there appeared in Germany, almost simultaneously, the works of Günz, Mauchard and Vogel. Günz reproduced Garengeot's theory, furnished exact anatomic descriptions of various sheaths for the different ruptures, described also those into the oval orifice. Mauchard tried experiments to ascertain the possibility of displacing the peritoneum. Vogel is credited with the important remark that strangulated hernia does not necessarily lie in the inguinal ring, but often in the hernial sac, even in the protruding viscera at times; I have not found the place in his book where it says so.

Regarding the treatment of reducible hernia, we have read, in the second chapter, of the outrageous malpractice carried on by the lithotomists with the radical cure. In the middle of the century Sharp and Günz favored the "king's suture," a method so-called because by sparing the generative organ its procreative power would be preserved and thus save subjects for the king. Vitriol was recommended by Renton for cauterizing, and in the year 1774 was again used by Maget and his friend Gauthier, who caused a great sensation with his ill-reputed writing. In it a thorough cure of all ruptures, no matter how large, was assured, taking for granted that they had not grown to any of the organs or the walls; but the details of the operation were concealed. The Académie de Chirurgie used its entire authority against the same; and above all others, A. Petit, who accused Gauthier of the famous de la Condamine's death; also Bordenave opposed him, although it appeared that both of these men were somewhat the victims of envy and jealousy. A third method of the radical cure consisted not only in compressing the neck of the hernial sac but to produce a counter-irritation to incite an adhesion. This was accomplished by means of a truss with a hard pad which was tightly put on the tumor and allowed to remain until intense pain ensued; then a softer pad was substituted. The closing of the neck of the hernial sac could be achieved by operative interference, if its anterior surface was scarified to cause an inflammation and then closed by a light weight truss. There was also a method extant to separate the hernial sac from the cellular tissue of the testicle and tie it close beneath the abdominal ring or return it into the abdominal cavity (Petit–Arnaud). Subligation Schmucker deemed the most reliable method of the radical cure and, on account of employing this in an operation on the body physician Zimmerman, became involved in a quarrel with Richter. The radical cure was often successfully carried out by Acrel, but he, like Petit and Sharp, saw patients die with it. He asserted that in many old ruptures the abdominal ring had been so greatly distended, that the best truss could not keep back the rupture, while by means of the operation, the same, if it could not be closed, could at least be sufficiently narrowed to permit of the use of the truss afterward. Operative interference in reducible hernia was opposed by Pott, B. Bell and Richter. The last surgeon rejected it entirely, with a few exceptions, having known the easiest, simplest and quickest operation to end fatally; and according to J. L. Petit's view, it was more dangerous than in strangulated hernia. Of course, Richter admitted the possibility of obtaining a complete cure with the aid of a truss and caustic and scarification of the neck of the hernial sac, yet all methods were uncertain and perilous. For the opponents of the radical cure there existed no other method but the truss, for the shape and application of which Richter's directions were very accurate. The inelastic rupture bands, which were very popular for a time, he absolutely rejected, and he had no use for the movable pads. The truss should always be put on by the surgeon the first time and then worn by the patient day and night. There was a difference of opinion regarding ruptures in children. Mohrenheim advised not to use the truss, the child being too weak to stand it; besides, the band would ever be wet through with urine. He gave wine with sal ammoniac, had enemas administered daily and saw the hernia disappear gradually. Pott, on the other hand, ordered every child, however young, to wear a truss of feathers; he thought the prevalent idea that it was impossible for a child to wear one, erroneous.

In strangulated hernia we follow especially Richter's methods. The cause of the strangulation was most frequently located in the abdominal ring, which, consisting of sinews that were continuations of the m. obliq. ext., might become constricted. A second cause, probably first observed by Saviard, arose from the constriction of the neck of the hernial sac due to the thickening and callosity of the same (resulting from pressure caused by the truss, Monro), also an aperture in the hernial sac, sustained through injury (Garengeot); or a partition wall in the same (Mohrenheim) could constrict the intestine; likewise the omentum becoming twisted with a portion of the intestine and driven into a pre-existing hernia (Callisen), or the hardened omentum pressing upon the intestine (Pott). Often the excrement was the cause of the strangulation. Richter distinguished an inflammatory strangulation, one caused by excrement, and added a third, the spasmodic. In this, the symptoms, with their intermissions and exacerbations, were mitigated by quieting remedies. It was often very difficult to determine the cause of the strangulation, which could also be conditioned by acrid bile and worms, and yet the success of the cure depended upon it. "Rational treatment of strangulated hernia requires far more knowledge and skill than an operation," Richter proclaimed to the surgeons.

There were various curious methods of taxis. One of the most favored was to tie up the patient to a strong man in such a way that his knees rested on the shoulders of the latter, the body hanging down from him (Sharp, Morand, Louis). The pressure, at first mild, was gradually increased, continued for a long time, and in inguinal ruptures was effected from below toward the top and from the inside toward the outside against the abdominal ring. Another manipulation consisted in pressing all parts of the entire rupture toward the inside toward the center of the swelling; a third method was to draw out the rupture and unfold the intestines; particularly was this used when there was an accumulation of fecal matters. The fourth manipulation, especially adapted to small ruptures, was to place one or two fingers at the side of the neck of the hernial sac on the abdominal ring and gradually press them back into the cavity of the abdomen.

Richter demand [illegible] is be c[illegible]d for an hour, but called attention to the exaggerated desire on part of the surgeons to continue the pressing in the following words: "Although I am free from being inclined to absolutely reject taxis, I must confess, pursuant to my experiences, that I think less of that manipulation than do the majority of the surgeons who consider it the principal method; and I am convinced that it is often harmful, seldom successful, but if successful seldom effects a complete cure. Rarely have I seen that a highly dangerous form of strangulated hernia could be returned into the abdomen, and in cases where it was returned, so many other remedies had assisted to mitigate the conditions, and after the preceding fruitless attempts the rupture retreated so unexpectedly and easily that I was always inclined to believe it would have gone back after a few hours, of its own accord." Likewise Pott did not strictly rely on the taxis, as at times it could be successfully employed after a week, and in other cases death ensued the same day. Desault considered it of great value never to employ the taxis immediately after the strangulation, as had been the general custom, but to precede the same by baths and softening poultices; furthermore it should be carried out very gently, since after vigorous manipulations the operation usually ended fatally. "There is always hope in a rupture that has not been touched before the operation." Unfortunately nearly every consulting physician who had been summoned allowed the tumor to pass through his hand, pressing it with great delight. If the entire hernial sac, the neck of which was constricted, with the intestines had been returned into the abdominal ring then the strangulation could continue. This fact had been observed by le Dran, la Faye and Arnaud, who produced dissections to prove the same. Louis, on the other hand, considered this reposition impossible on account of the firmness of the cellular tissue between the hernial sac and the testicle, and on account of the abdominal ring being too narrow; in short, he was very much in doubt about it, because he did not understand the matter. This vexed Richter and he replied: "If everything that we can not explain is not true then 100,000 truths which are daily before us would be false and we would no longer have the sun. But if in spite of this fact Mr. Louis continues, and because he can not comprehend the matter declares it an impossibility, and thereby intimates that the aforesaid three surgeons had fabricated their observations, then he is guilty of great impudence, and I, for my part, must confess that I by far more appreciate the experience of an Arnaud, the greatest authority on hernia that ever lived, than all the theories and over-refined reasonings of Mr. Louis, and that to me the trustworthiness of a le Dran and la Faye is of greater importance than all the assertions of Mr. Louis."

Various internal and external remedies are used to assist the taxis. Mild purgatives (Epsom salts according to le Grand's directions. or a decoction of herb nicotian. and rhubarb) were recommended by Richter in strangulations due to excrement and worms, but he advised against them in case of inflammations. Pott, however, did not think much of purgatives, because the constipation resulted from the constriction of the hernia, therefore the treatment must be directed toward the latter; according to Bell's and Wilmer's ideas they caused more harm by irritating the intestine and increasing the vomiting. Among the injections the one of tobacco smoke was thought the best, especially in spasmodic strangulations. It is said that Heister was always so successful in employing it that he never found an opportunity to perform the hernial operation. Yet there was a difference of opinions. While a few obtained good results but seldom from the use of the tobacco enema (B. Bell), or rejected it altogether and used water instead (Latta of Edinburgh), others were full of its praise (Pott, Wilmer, Richter). The last surgeon demanded that the smoke of a good and strong tobacco be blown into the hernia for at least an hour. For "this is the most common error on the part of surgeons in strangulated hernia; they like the frequent changes in methods and do not use one persistently, and yet there is seldom one that affords a speedy relief; generally we gain our purpose only by persistence." Injections of cold water and vinegar were also recommended (Theden). Of the antispasmodic remedies, the tepid baths chiefly assisted the taxis. It was always the first method employed by Desault; the baths were given two or three times daily, lasting for hours at a time. With the aid of warm baths, poultices and plain injections, Desault saw serious strangulations disappear without necessitating a taxis. Then linimentum volatile was rubbed in and poultices of camomile and linseed applied, for internal use ipecacuanha and poppy juice were given. General bleeding to the verge of faintness was the method resorted to in inflammatory strangulations, which was rejected by a few who did not see the taxis succeed through the exhausted condition (Wilmer, Alonson). Warm poultices, especially indicated by spasmodic and fecal strangulations, Richter ordered put over the entire abdominal region, not on the rupture alone. Many parties opposed the same (Pott, Monro, B. Bell, Wilmer and Keate). They did not think much of the poultices because the effect produced did not penetrate deeply enough, because the intestines were distended and the swelling increased. Pott even believed that the faith in them on account of the irretrievable loss of time had killed more people than saved them. Instead of warm poultices cold compresses were advocated. These (according to Richter) "incited the intestines to greater activity, thereby distributing the excrement and flatulence, contracted the blood vessels, freed them from the impeding fluids, reduced the size of the rupture, mitigated the pain and assisted the return of the hernia into the abdomen." The rupture and the limbs were suddenly treated to a shower bath of ice-water (J. L. Petit, Arnaud), or poultices of ice were made (Monro, Richter, Schmucker, Theden). Also by means of sugar of lead, water mixed with vinegar (B. Bell), by a solution of sal ammoniac (Wilmer), and evaporation of ether on the rupture (Hughes), frigidity was produced. Richter thought it contra-indicated by serious inflammation and violent pain, and by spasmodic strangulation, but wished this method only as a last recourse for a few hours when all others had failed.

When all methods proved of no avail, the operation became a necessity. But when was it to be performed? To designate the proper time, Sharp considered a more difficult task than to accomplish the operation, and Pott held the opinion that there was probably no subject in surgery which required greater power of judgment, more firmness and care than was necessary to determine the period beyond which it would be dangerous to defer the operation. By the majority of the German surgeons the operation of herniotomy was carried out too seldom and too late.

They experimented principally with internal and external remedies in the hope of diffusing the hernia, and tried everything imaginable. Thus, precious time was wasted, the symptoms increased in intensity and then came gangrene or mortification. The reason for this delay is found in the fear of resorting to the knife. It was otherwise in France, where, in the 90's, herniotomy was performed unusually often and the taxis seemed to have been neglected. Desault is credited with the honor of having revived herniotomy. At one time eleven whom he had operated on died in succession, while at another time fourteen patients similarly treated survived the operation and recovered. All good surgeons were convinced that it was best to operate immediately if the symptoms did not abate after applying the usual remedies for several hours. Pott asserted that if the operation was performed at the proper moment it would always fulfil the desired purpose, and believed himself justified in saying that not one case out of fifty would prove fatal if the operation be performed carefully and in good season. B. Bell wished all treatments energetically applied, but never longer than three or four hours, to be followed at once by operative interference; every minute of delay increased the danger. This principle was followed in Germany by Heister, Bilguer, Steidele and Richter, who said: "It is better to interfere too early than too late. The operation is in itself not dangerous nor very painful. The danger is not the result of the wound, but is generally caused by the length of time it is deferred. As soon as the hernia becomes so painful that a slight pressure can not longer be borne, no time must be lost and the operation must be performed, partly because the rupture is already highly inflamed and the danger of gangrene not far distant, and partly because the palliative methods are of no more use. . . . The smaller and the more recent the hernia, the more tightly constricted is the strangulation, the more pressing the danger. . . When all methods vigorously applied have been fruitless the operation should be made without delay. The strangulation is worse tomorrow than it is today; hence, tomorrow these remedies will avail less than today." Pott reasoned similarly and said that no one can tell when a hernia becomes mortified. For several days the strangulated intestine might remain well and then again it might be gangrenous within twenty-four hours after the protrusion. Steidele had a similar experience of finding a hernia mortified, although the symptoms were very mild, the fever scarcely perceptible and the pain endurable. The cause of Morand's exceptional success in herniotomy was that he never deferred the operation long and preceded it with a mild taxis two or three times.

Concerning the technique of herniotomy, the incision was made above the abdominal ring, penetrating to the bottom of the tumor (Louis). Opening the neck of the hernial sac was, since Garengeot's time, universally believed to be necessary. Upon his and Mauchard's advice, the knife was held obliquely and the several layers of the cellular tissue separated by raising each one with a pair of forceps. Pott and Richter split the hernial sac upward, but not, as was usually taught, to the abdominal ring, but only within an inch or an inch and a half beneath the strangulation, only far enough for the finger to enter. As a living probe Richter considered the finger the safest means to prevent all injuries. If the hernial sac was very large, a portion of it could be cut off; the ligature recommended by Günz, Pott disapproved of. Light injuries were not considered as dangerous by Richter as many others believed them to be; they could be returned without any symptoms. "I am not all inclined to induce the surgeons to become inconsiderate and audacious, but I think it is my duty to encourage them when I see them being instilled with fear without a cause." The mode of procedure of not opening the hernial sac and only distending the abdominal ring was a method already used by Franco, who was the first to operate on a strangulated hernia (1561), and by Paré, but was not introduced into the practice of medicine until later by J. L. Petit. Consequently it bears his name. He had practiced the method for more than thirty years, refuted all objections and laid great stress upon there being less danger, no contact of air, etc. He protested that he did not reject the opening of the sac in every instance, for there was no question that it was necessary in gangrenous hernia. Petit's method, however, was not generally adopted. With the exception of A. Monro, Vater, Acrel, Richter and J. G. Wagner, the method was rejected by all the surgeons of the various nations. They cared nothing about it on account of the intestine and the omentum adhering to the sac, the eventual mortified condition of these parts, also the easy relapses, and the putrid fluid of the hernia. Pott regarded this method very contemptuously, spoke of writers who mentioned things of which they had no experience, but what they produced one copied from the other; he had but little to say of it and did not consider it worth his while to subject it to an examination. Richter compromised matters by saying: "It has become a sort of duty in these modern times to reject this method absolutely and in all cases. The one has repeated the words of the other, no one heeding the inventor's purpose and the cases in which he recommends them. The reasons for not opening the hernial sac are truly striking, but they are by far not so good and demonstrative as many seem to think. Ordinarily there is too much praise and too much censure. This method is not practicable in all cases, nor can it be positively rejected in all cases. Besides, the inventor did not intend its general use; he recommended it in special cases only. The idea of the general utility of this method seems to have been forced upon Mr. Petit, and at the same falsely attributed to him so as to be able to reject it. I hold the opinion that this *modus operandi* ought not to be rejected in all instances but employed wherever it would be of use and advantage and be permissible under the circumstances." Contraindications to him were adhesions of the parts in the rupture; great thickness of the hernial sac so great that on the outside of the same no instrument could be inserted for the distension of the abdominal ring; also, gangrenous hernia and strangulation in the neck of the hernial sac.

For extending the abdominal ring the incision was either made toward the navel (Heister, [illegible] Bertrandi, Richter), or toward the outside [illegible] (Sharp, Pott, le Faye). Desault was [illegible] ating by the position of the spermatic [illegible] canal; if it lay behind or inside the sac [illegible] upward and outward: if it [illegible] the sac he distended the opening [illegible] The instrument used for the [illegible] scalpel with a dull and [illegible] (Richter), or the well known [illegible] this operation the French invented a number of useless instruments (Méry's winged sound, Morand's hernial bistoury, le Dran's hernial bistoury and other instruments). The knife was pushed in on the hollow probe, or on the finger, allowing it to press more than to cut. The distension sufficed, if it permitted the admission of the finger in the abdominal ring. Le Blanc and Arnaud wished to insert the finger and the hook, respectively, in order to distend the abdominal ring. This method was rejected by most of the surgeons. B. Bell considered it *next to an impossibility*, because Poupart's ligament was already so stretched that it was not capable of being distended any more, and Louis ridiculed such procedure. But Richter advocated the method in femoral hernia, so as to avoid the danger of injuring the epigastric region or the spermatic vessels: "I can not easily make up my mind to cut into the Poupart band in males, but will ever strive to widen the ring by this method. In inguinal hernia this method may be dispensed with, because then the cut can be made without danger, and yet the method ought not to be absolutely rejected." Intestines that had become discolored, either deep red, brown, or even black, could be successfully returned into the abdominal ring (Desault, Schmucker); only when they had become disgustingly mortified could they be treated as gangrenous hernia. After the reposition, Richter deemed it advisable to scarify and compress the neck of the hernial sac, thereby sometimes effecting a radical cure. After the operation a T-bandage and, during the entire treatment, dry charpie was applied, besides which fomentations were put upon the abdomen and mild purgatives as well as injections were given. If a part of an intestine had become gangrenous, it was fastened on the outside of the abdominal ring by means of a thread drawn through the mesentery; then the gangrenous portion was cut out and the sound portion reposited. But if the mortification covered a large surface, joining of the parts was *not to be thought of unless both ends of* the intestines protruded from the abdominal ring, otherwise all was left to Nature. La Peyronie and Ramdohr invented special intestinal sutures; du erger joined both ends over the dry trachea of a goose one another, etc. J. L. Petit principally favored e *idea that* Nature *alone* effects a cure, for he had seen several gangrenous herniæ heal almost without artificial means; therefore he thought most remedies for joining superfluous, yes, even dangerous. Richter held the same opinion. In an intestinal fistula he ordered a common elastic truss worn and under the pad of which a sponge or wad of charpie was placed on the opening. There was much dispute in regard to the treatment of the abnormal omentum. The first method used was the ligature. Most surgeons favored cutting it off and rejected Arnaud's special method of tying it off. At the most it was allowed when greatly developed arteries promised violent hemorrhages in connection with the incision. The dead portion of the gangrenous omentum was cut out and then it was returned, or if this was not possible it was left lying in the neck of the hernial sac; also the hardened omentum was left alone and only the abdominal ring distended in order to raise the strangulation.

Space does not permit us to enter more fully into the various kinds of hernia. The true nature of the congenital rupture was first determined by Haller, and William Hunter improved upon his work. There originated with Richter, for umbilical rupture in children, a bandage still used, which consisted of half of a nutmeg wrapped in linen, the application of which with the assistance of plasters and strips he described clearly enough, so that he alone merits the honor of the invention. For adults he suggested a special kind of umbilical truss. For the radical cure of hernia Desault resurrected the ligature heretofore recommended by Celsus, and prized it as a reliabe painless as well as safe method in the tenderest age of a child; this mode he had successfully used more than thirty times in the Hôtel Dieu within eighteen months. In femoral hernia, in which Gimbernat thought the seat of the strangulation located in the crural curve of the m. obliq. ext., to avoid the epigastric region the direction of the incision should depend upon the position of the rupture. If situated on the inner side of the femoral vessels the incision was directed obliquely toward the linea alba (Günz, Camper, Richter) and as closely as possible to the inner angle of the fissure. If the hernia lay on pulsating vessels or outside of them, then the cut was made outward and upward in the outer angle of the fissure. Wilmer cut directly upward, while B. Bell made several small incisions. If the epigastrica was injured, which was considered a very dangerous matter, it was necessary to interfere very energetically to reach the vessel, compress the same by means of Chopart's forceps, or ligature in order to stanch the flow of blood.

SOCIETY PROCEEDINGS.

Chicago Academy of Medicine.

Stated meeting, Oct. 15, 1897.

Dr. G. FRANK LYDSTON in the Chair.

The subject for discussion was "Hysteria," which was opened by Dr. BANNISTER.

DEFINITION OF HYSTERIA.

Dr. H. M. BANNISTER—The average conception of hysteria by those who have not given the subject more than casual attention is probably an indefinite one. It is considered as a condition without a very precise definition and into which may be thrown an infinity of morbid symptoms that can not well be referred elsewhere. The definitions that are given of it also show a considerable variety. Quoting only the most recent ones the following may be offered:

Lowenfeld says that it "is a general neurosis in which nevertheless a peculiar participation of the cortex or a primary predisposition renders possible a reference of a part of the symptom to the psychic sphere." Bartholow defines hysteria as "a functional nervous trouble characterized by various motor, sensory and intellectual disturbances, and by excessive variability in their seat and manifestations." Landon Carter Gray calls it "a peculiar increased reflex excitability of the cerebro-spinal nervous system, possibly also of the sympathetic, with decrease of cortical inhibitory power." In one of the most recent text books, Dr. J. Hendrie Lloyd defines hysteria as "a psychoneurosis of which the physical symptoms are the most conspicuous, tending to disguise the mental phenomena and to simulate superficially the effects of various organic diseases."

Of those who consider the disorder more especially a psychosis in its pathologic sense, or a mental disease, following the example of Charcot, I will quote the following definitions: Moebius defines as hysterical "all those alterations of the body which are produced by ideas." Osler, quoting Moebius, gives as his definition "a state in which ideas control the body and produce morbid changes in its functions." Oppenheim's definition is as *follows*: "*A mental disease that* reveals itself not in intellectual disorders but in anomalies of character and emotion and conceals its real nature behind an almost unlimited number of physical symptoms."

It will be seen that in these definitions there are embodied two conceptions of the disorder; one that it is a neurosis, understanding by the term a disease of the nervous system of rather indefinite nature and pathology, and the other that it is in the proper sense of the word a mental disease. All mental disorders depend upon the derangement of function of the organ of the mind, or the cortical substance of the brain. For myself I would adopt the view of those who consider hysteria a mental disorder and would offer as a definition, which I do not consider, however, as necessarily better than those that have been given, but simply as conveying my present conception of the condition, the following: Hysteria is the manifestation of an original or acquired degeneracy in an ill-equilibriated action of the various cortical centers, characterized by lack of inhibition and heightened suggestibility. Reduced to its simplest expression this definition might be stated as that hysteria is an undisciplined functioning of the cortex. This, however, is not a perfectly accurate condensation.

The essential of hysteria as a disease is a degenerative basis. Every one has in him or herself the potentiality of hysteric symptoms, and under special stress of circumstances any one is liable to manifest them. But it is only in degenerates, and in proportion to the degree of degeneracy that it becomes a disease.

RELATIONS OF TRAUMATISM TO HYSTERIA.

Dr. Hugh T. Patrick—The questions of most practical interest regarding the relation of traumatism to hysteria are two in number: 1. Does traumatism cause hysteria? 2. If so, does hysteria of this etiology differ from that due to other causes? Each question is to be answered in the affirmative, with certain qualifications.

For any morbid influence to produce disease there must be a susceptibility or a vulnerability of the organism so proportioned to the noxious agent as to allow of its domination. This axiom applies to hysteria as naturally as to fracture, toxemia or vicious education. In current parlance, then, traumatism may be the exciting cause of hysteria. But there are many diseases in which the exciting cause constitutes practically the entire etiology. A violent blow properly administered will invariably break the human fibula, and the injection of strychnin in a sufficient dose will be uniformly fatal. In such instances, however, the fragility of the bone or the comparatively feeble resistance made by the nervous system to the overwhelming power of a poison can not be regarded as a predisposing etiology, because the strength and vitality overcome are up to the normal average vigor of our present physical status. Is the case of trauma and hysteria somewhat analogous? In brief, may traumatism cause hysteria in a normal person? I shall certainly not assert that this can not be, but I believe that such an occurrence must be of an extreme rarity and I can state positively that an indubitable instance has not come within my personal knowledge. To enunciate a rule, then, in answer to the first question, it may be said that traumatism may cause hysteria, but, as a rule, only in persons with a certain abnormal somatopsychic susceptibility. For the practicing physician it is of considerable importance to know whether this morbid frailty can be affirmed in individual cases. In my experience it can, if a fairly good history be obtainable. Evidence of nervous instability, of nervous symptoms out of proportion to the cause, or of foregoing outspoken hysteria will become patent to the expert inquirer.

In attempting to designate the distinctive traits of hysteria excited by trauma, if any such exist, the subject may also be approached by the etiologic gate. Whether or not hysteria be a well defined pathologic entity, the ascendance of the more striking features in each single case are largely determined by the nature of the exciting etiology and the circumstances of its application. It is true that "traumatism" covers a broad domain of physical and mental injury associated in a melange of infinite variety, and imperceptibly loses its identity in related morbific agents; still, in the ordinary course of human affairs, it possesses certain leading characteristics by which it is currently and readily recognized as a something apart. So the hysteia of traumatism, while it can be said to present no single pathognomonic sign and, in an absolute ignorance of the etiology, it can be asserted of no case of the disease that it has been excited by traumatism and by traumatism alone, yet as a group, the traumatic cases may be said to present a certain somewhat vague but perceptible facies and to evidence somewhat characteristic tendencies. The most prominent of these distinguishing features relate to localization, pain, the admixture of symptoms of neurasthenia, hypochondria or melancholia, the rarity of general convulsions, to tremor and backache.

In the nature of things a traumatism injures one part of the body more than others and in harmony with an etiology more or less locally defined in its application, the more salient symptoms of traumatic hysteria are apt to be local, the point of injury determining the place where the more obtrusive of these will be manifest. Hence, monoplegia, localized spasm, isolated amblyopia and regional anesthesia are relatively frequent.

Almost a universal accompaniment of traumatism is pain, and hence it would be but natural to suppose that pain would be more constant and severe in hysteria caused by injury than in the same malady due to higher or more purely psychic influences. Experience has shown this to be the case.

As before noted, traumatism, with the immediately succeeding mental and bodily states, involves a most complex concatenation of pathogenetic influences and it is no wonder that the results are so widely discrete; the individual cases of consequent nervous trouble so atypical. In brief, with so mixed an etiology, a mixed clinical picture is inevitable, hence the anomalous so-called hysteroneurasthenia, hysteromelancholia, neurasthenomelancholia, etc. It is for this reason, I think, that the patient hysteric from trauma, is apt to show the ready exhaustion, agorophobia and irritable weakness of the neurasthenic or the depression and lack of courage of the melancholiac, or both.

Traumatism rarely causes a powerful and general mental commotion without the intrusion of particular bodily harm, which would probably explain, what I believe to be a fact, that general convulsions (hystero-epilepsy) are somewhat rarer in traumatic hysteria than in other forms of the disease; but it is not uncommon for a scar or point of injury to constitute a so called hysterogenic zone, pressure on which will cause a hysteric convulsion.

Tremor of some kind or another, often reaching in degree a marked shaking or jerking, is seldom absent in hysteria from trauma, and the relation of this symptom to the etiology seems clear. It is physiologic for a person physically or mentally shocked to tremble, especially after the moment of impact, when reaction and realizing consciousness supervene.

Finally, there can be no doubt that pain in the back, more or less spinal rigidity and tenderness along the vertebræ are more frequent in the traumatic cases than in others. The *rationale* of this prominence of back symptoms is obscure and I would not wish to speak positively on the subject, but I am quite willing to express a tentative opinion. The evidence tends to show that man was not always a biped; to stand erect is not always his prerogative. The dorsal and lumbar muscles and the vertebral ligaments are amply sufficient to maintain the perpendicular station under favorable circumstances, but they have not yet become equal to all the exigencies arising from modern civilization. The spinal column and its appendages are somewhat behind in the process of differentiation and specialization constituting development and thus remain a *locus minoris resistentiæ.*

THE RELATIONS OF HYSTERIA AND EPILEPSY.

Dr. Sidney Kuh—Both hysteria and epilepsy are degenerative diseases of the brain. Therefore, they both develop most frequently in those whose central nervous system is congenitally weak. In both diseases the exciting causes may be the same. Violent emotions; injuries; intoxication with lead, alcohol, nicotin, morphin; acute infectious diseases; certain constitutional diseases may precede the first symptoms either of epilepsy or of hysteria. The influence of menstruation, pregnancy, the menopause, venereal excesses, overexertion upon both neuroses has been known for a long time. But even as we study the etiology of the two diseases, the fundamental difference between them becomes evident. Who has ever heard that a faulty education, that idleness had caused the signs of epilepsy to appear, two factors which undoubtedly play a most important role in the causation of hysteria and afford a satisfactory explanation for the pronounced prevalence of the latter trouble among the female sex in most civilized nations as well as for the remarkable fact ascertained by Briquet, that hysteria is very much more common in those religious orders in which all day is devoted to prayer and pious thought, than among those nuns who are active in nursing and in other charitable work.

While epilepsy seems to be a disease that has found its victims among all races and at all times, hysteria is more probably a relatively recent acquisition of humanity, one that came only with civilization and one with which even today the more barbarous races have barely met. The similarity in the symptoms of the two diseases is due to the fact that both must be localized in the same portion of the nervous system, and that both are in the majority of cases due to a congenital weakness of those organs. Hence both the hysteric and epileptic character have certain traits in common with that of the degenerate, and until the secondary mental changes due to frequent epileptic seizures develop, the epileptic, the hysteric and the degenerate are mentally very much alike. If there is any difference between them, it consists in the fact that in hysteria the exaggeration of self-consciousness, emotionalism, craving for sympathy and exaggeration of suffering, are more pronounced than in epilepsy, that in the former trouble there is occasionally a great display of, usually misdirected, energy or of theatrical unselfishness, which does not occur in epileptics.

In both neuroses, psychic and motor symptoms occur simultaneously, but in epilepsy the motor, in hysteria the mental phenomena prevail. How strongly hysteria is influenced by the mind is shown by the occurrence of epidemics of that disease. It is true that the witnessing of an epileptic seizure in another person does occasionally produce a spasm in a predisposed individual, but who has ever heard of such epidemics of epilepsy as we read of in the history of hysteria in the Middle Ages and witness occasionally in our day in girls schools and cloisters. It is the psychic element, too, that is responsible for the frequent changes so characteristic of most cases of hysteria, while in epilepsy the symptoms, though most of them occur only periodically, are in the main constant and unvarying. In the so-called hystero-epileptic seizure the mental element is evident in the "attitudes passionelles."

In their effect upon the human organism the two diseases differ widely. Neither the single hysteric attack, nor a series of them produce the same disastrous results as the epileptic fit. In the one stupor, violent headache and complete amnesia usually follow the explosion; in the other amnesia is as rarely complete as it is incomplete in the epileptic, and mind and body appear none the worse for the preceding violent exertion. In the one we see a series of attacks, a *status epilepticus* accompanied by hyperpyrexia; in the other, attack follows attack with no elevation of temperature at all, or at the worst only a slight one. The one disease exists for a lifetime, without reducing the mental condition to a lower level than it was at the beginning of the trouble; the other often within a few years, reduces the sufferer to a state of pronounced dementia.

All of this tends to show that while both neuroses are due to changes in the same organ, the nature of these lesions must be totally different. Epilepsy is a disease which we are today hardly justified in counting among the functional maladies. For besides those pathologic signs due to degeneracy, as asymmetry of skull and face, malformation of palate, irregularity of teeth, adherence of lobules of ears, etc., which are common to all troubles arising upon that same basis, we find organic changes in epilepsy, such as we do not see in hysteria. Chaslin, Féré, Bleuler and others have described hypertrophy of the neuroglia in certain parts of the brain, and one of these authors (Bleuler) states that this lesion, while distinct in the brains of all of his twenty-six cases of epilepsy, was not found in any of the fifty-four cerebra of non-epileptics. While there is some similarity in the etiology of epilepsy and hysteria, as well as in their symptoms, due to the fact that both neuroses are ascribed to the action of similar conditions upon the same organ, they are pathologically as widely different from each other as a diabetes inspidus is from chronic interstitial nephritis.

ABDOMINAL RELATIONS OF HYSTERIA.

Dr. F. S. Coolidge- I can not believe that hysteria is caused directly by any derangement of the sexual organs. I believe, however, that certain derangements of the sexual organs by their repeated irritation can bring about such a state of the nervous system in a person who has a taint toward hysteria, that the taint becomes manifest and hysteria develops. You will remember that Stevens thought that eye strain was the cause of epilepsy, and that by cutting the muscles of the eye epilepsy could be cured. He failed in the majority of cases, but in some cases he was successful in relieving epilepsy by removing the exciting cause, the constant irritation of the nervous system, although the epileptic taint was still there ready to reappear should any other exciting cause manifest itself. So with reference to the abdominal and gynecologic relations of hysteria, I think in certain cases, if we can overcome the derangements of the sexual organs and do away with the constant irritation of painful menstruation, and other nervous phenomena incidental to them, we may often be able to materially relieve hysteria. But the old belief that hysteria was undoubtedly due to the sexual organs, and that the removal of these organs would cure hysteria, is passing away. Bushels of healthy ovaries, and tubes have been removed under that belief, and it is a fad that is yet running in certain localities. Recent statistics, however, disprove this theory. The most recent statistics I have seen are those given in the *Boston Medical and Surgical Journal*, in an abstract of a paper by Dr. Angelucci of Italy, who collected his statistics from asylums where the patients could be watched, and not where they were operated on in a hospital, then dismissed, or discharged as cured, no further record being kept of the patients. He collected forty-one cases which were operated on for pure hysteria, in which healthy organs were removed for the purpose of curing the disease. Of these forty-one cases, seventeen became insane, ten became worse, eleven were unaffected by the operation and three were cured by it. In other words, nearly three-fourths of the forty one cases either became insane or grew worse, and only three were cured. Of eighteen cases in which diseased sexual organs were removed, three became insane, six were not affected one way or the other and nine were cured. At the same time he collected six cases of pure hysteria in which a pretended operation was done, namely, a laparotomy, or possibly an incision not going through the peritoneum. All of these cases were cured.

It seems to me there is reason for this. In the first place, by removing the sexual organs, the ovaries and tubes, or the ovaries alone, there is brought about the menopause; and the menopause even in normal life produces what we might call a nervous shock, this shock extending over a period of some time causing a nervous condition which is of certain importance in the life of any woman. Not only does the menopause bring about a nervous shock in normal life, but if brought about early, by operation, the shock is augmented. This is one explanation why, in these cases of hysteria oophorectomy, with or without removal of the uterus, three-fourths of the patients are made worse. The operation produces a nervous shock in addition to the hysteria which is already present and makes the patient worse. In the case of unhealthy tubes and ovaries removed for hysteria, one-half are cured and the other half remain either unaffected or are made worse. In them we have dealt not with the true cause, but only the exciting cause of hysteria. In the six cases of hysteria in which a pretended operation was done, all of which were cured, we had the influence of suggestion.

So in any operation of this kind we have the value, on the one hand, of the influence of suggestion against, on the other hand, the bad influence of induced menopause, if I may so call it, and much in accordance with Angelucci's statistics, the feeling at the present time is that the suggestion caused by the operation is not of as great value as the harm done by removing healthy ovaries. My belief at present is that it is absolutely wrong to operate for the removal of the ovaries in cases of hysteria unless there is sufficient disease in those organs to warrant it, and it is only in those cases in which the diseased organs are presumably the exciting cause of the hysteria that such an operation is justifiable.

I have had one experience in removing the ovaries of a woman who had difficult menstruation. The hysteria at all times was marked, but particularly so at the menstrual period. She died of acute mania on the fourth day after the operation. It was a single experience, but it was to me a lesson.

To sum up: According to the present status of this subject, it is unjustifiable to remove healthy organs in cases of hysteria without any palpable disease of those organs.

AUTO INTOXICATION IN ITS RELATION TO HYSTERIA.

Dr. W. A. Evans—By the term auto-intoxication I mean the poisoning of an individual by the poisons that he himself produces. It does not include poisons produced by bacteria or other organisms in any of his cavities, and whose absorption he does in some measure control. It does include products of incomplete digestion or incomplete assimilation, the incompleteness being due to his fault or condition. For example, if by change in intestinal epithelium proteoses are not converted into serum albumin, or if anti-peptone is not transformed by liver cells, intoxication results. It then does not include intestinal putrefaction. It does include poisoning with leukomains and with proteoses and anti peptones. Auto-intoxication can produce hysteria. Hysteria can cause auto intoxication. Auto-intoxication can produce hysteria by changing the anatomy and physiology of the higher nervous centers so that they lack "balance," or by upsetting an equilibrium rendered unstable by this or other causes. Hysteria can produce auto-intoxication by excessive leukomain production, *e. g.*, by violent nervous or muscular effort, or by diminished excretion, *e. g.*, hysteric anuria.

THE ORTHOPEDIC ASPECT OF HYSTERIA.

Dr. John Ridlon—It is more than likely that hysteria may simulate any disease or deformity in the province of the orthopedic surgeon. Personally, I have met with only the following: The hysteric spine may be mistaken for spondylitis or for scoliosis. In simulating spondylitis it may have a posterior curvature, but never a posterior angle. The spine may be more or less rigid, but the rigidity is rarely confined to the posterior curvature, and it is not equal in all directions, that is to say, there is often normal motion in one direction. The range of voluntary motion is greater than the range of passive motion, especially if the patient's attention is directed elsewhere. Pain is usually local, whereas the pain of spondylitis is distant. Tender points along the spine are always, or almost always, found in the hysteric spine, and never found in spondylitis unless there be such local manifestations of inflammation as the development of an abscess. The hysteric spine is usually accompanied by other manifestations of hysteria.

When the curve of an hysteric spine is lateral it may be said to simulate scoliosis. In such cases it presents all the symptoms above enumerated, whereas a true scoliosis presents rigidity only after years of deformity, never presents local tenderness, and rarely either local or distant pain.

Simulating hip disease, it often presents very great rigidity without deformity, whereas in hip disease the deformity develops step by step with the rigidity. To passive motion, the rigidity of the hysteric hip is uncertain and shifting and has an elastic feel; the rigidity of true disease at the hip is always a fixed quantity at any single examination, that is, it is never more and never less, though it may be greater (or slightly less) at a second examination some days later. There is usually local tenderness, which is rare in true disease except during the formation of an abscess. The pain is usually at or about the joint; the pain in true disease is usually at the knee. Muscular-atrophy is not present in hysteric hip; it is a constant symptom in true disease.

The same symptoms may be applied when differentiating disease at the knee. But at the knee the differentiation is not so easy, since in some instances there is present a puffiness and false fluctuation which closely resembles beginning tubercular synovitis.

The same may be said of hysteria at the ankle joint.

When hysteria affects the tarsus it is more likely to simulate talipes equino-varus than tuberculosis of that part.

When hysteric equino-varus is present the resemblance to the deformity resulting from infantile spinal paralysis is very great. Indeed, it may even imitate a congenital clubfoot except for the history. In both instances atrophy of the leg muscles, from disease in the congenital form and from paralysis in the paralytic form, is found wanting in the hysteric case.

In all diseases of hysteric deformity, profound anesthesia would seem to offer the key to the problem; but it should be remembered that recent deformity due to tubercular joint disease may disappear under profound anesthesia and, on the other hand, prolonged hysteric deformity may result in a structural shortening of the muscles on the concave side, which does not yield to even profound anesthesia.

There should be no difficulty in differentiating true wryneck from an hysteric condition in this region. In true wryneck the only symptoms present are those depending upon a structurally shortened sternomastoid muscle, whereas the hysteric condition closely simulates cervical spondylitis, from which it must be differentiated by the rules laid down in discussing spondylitis and the hysteric spine.

HYSTERIA AND ITS RELATION TO PREGNANCY.

Dr. C. E. Paddock—"The causes that directly determine the development of hysteria in an individual may be either physical or mental influences, or both. Of the two, the mental and moral influences are the more potent and the most frequent. The only disturbance common to all forms of the affection is that of cerebral functions, and we are not justified in looking beyond these for the primary development" (Gowers).

The physical conditions that may influence the development of hysteria are many, but disorders of the generative organs have always claimed the most attention. "Some morbid state of these organs is present in many cases, but the estimate that at least one-half of the sufferers from hysteria are free from such, is probably near the truth" (Jolly).

It is evident that whatever influence disorders of organs may exert, they are really the manifestations of the disease already in existence. As the term hysteria implies some uterine trouble, it is probably one reason why so much importance has been given to that organ in this relation. The etymology of the term is therefore misleading. To define hysteria, an accurate description of the individual with the ancestry and environments which surround the particular person seems necessary.

That hysteria is prevalent in all classes of society is apparent, but that heredity, education, climate and environment have their influence, there is no question. In the higher classes of society, idleness, social duties, dress, a sedentary life, furnish sufficient reason for the development of the disease. In the lower walks of life, unless it be among the dissipated and vicious, hysteria is seldom known.

In mild attacks hysteria may be controlled or modified by the will, but when the hysteric habit has got control of a person, the least mental or physical fatigue may produce a fit of nervous excitement due to exhaustion of nervous force, and the patient is no longer able to control this paroxysm by will power. It is a mistake, therefore, to look at these cases as controllable. They can no more be influenced by the will and stopped than can an eclamptic attack. Hysteria occurring in the pregnant woman means more to the obstetrician than the same does in diseases in general. Pregnancy is considered a physiologic process, but only when it occurs in a woman free from disease. In every case of pregnancy when hysteria develops, I will prove to you a previous hysteric tendency.

The causes of hysteria in gestation are the same as in the non-pregnant woman. Authors generally agree upon this. "Playfair's System:" "A pregnant woman may suffer from hysteric convulsions, but this condition is identical with the same disease in the non-pregnant, and they are in no way special in their nature." "Gleson's Midwifery:" "Hysteria is quite common at the commencement of gestation and hysteric convulsions are most frequent at this stage. It does not differ from hysteria in the non-pregnant." Similar extracts may be taken from writings by Tarnier, Lusk, Galubin and others.

Professor Valenta, in the *Arch. Gynäkol.*, XLIX, Vol. I, p. 189, 1895, reports a case of hysteria in first pregnancy. The patient was in the fourth month, was very hysteric, and wished to get rid of the child. The case threatened to pass from a nervous to a psychotic state. Abortion was performed. As soon as the membrane was ruptured all signs of hysteria ceased. There was an absence of any pathologic condition of the genitalia, but that there was a lesion somewhere is proven by the further statement that the case had been hysteric from childhood. Her father died of delirium tremens, and her paternal aunt was insane.

I can quote cases, in my own practice, of pronounced hysteric tendency, increased perhaps from psychic and physical reasons, such as maternal impressions, vomiting, etc., but in all these cases we do not have to look far for a cause.

From my own observations I formulate the following:

1. Pregnancy itself is not a cause of hysteria.
2. Hysteria in pregnancy has the same primary formation as hysteria in any other form.
3. Heredity plays a very important part in its etiology, and the womb is no more a factor than any other organ which may be diseased.
4. Cases previously hysteric are not benefited by pregnancy, their offspring are alike hysteric and degenerate, and our social and moral obligations are not enhanced by bringing such children into the world.

HISTORY AND MEDICINAL THERAPEUSIS OF HYSTERIA.

Dr. Geo. F. Butler—The earliest medical conception of hysteria is presented by Shakespeare in Lear, when that king ere his madness says:

> "O, how this mother swells up toward my heart,
> Hysterica passio down, thou climbing sorrow,
> Thy element's below."

In this, Shakespeare fully represents the old conception of Hippocrates, that hysteria was due to strangulation by the womb. To this strangulation, which resulted not from the womb moving about, but from some supposed reflex nerve performances akin to those utilized so lucratively today, were due, according to the Greek physician, six hundred and odd disorders of various types closely allied to those now ascribed to hysteria. As the male, in the hermaphroditic conception of the Greeks, was supposed to have a "spice of the mother," as the womb was called equally by Greek, Celt and Teuton, Hippocrates, like Shakespeare, naturally finds these disorders in men also; a conception that was supposed to be peculiar to the nineteenth century. During the centuries down to the sixteenth, many diverse notions of hysteria obtained, varying between the limits observed today. Rislau, Diemerbock and Bonnet attempted to establish, in the sixteenth century, that relationship between the female genitals and hysteria which has proven so lucrative to *fin-de-siecle* gynecologists. Nearly coeval with Shakespeare, Harsnet showed that when devils were cast out by miracle, the alleged devil was merely *hysterica passio*. About this time Dr. Jorden, in a treatise on "Suffocation by the Mother,' strongly urged the reflex notions common to Hippocrates and modern gynecologists. In 1620 Lepois claimed a cerebral basis for hysteria. Indeed, during the sixteenth, seventeenth and eighteenth centuries, medical disputes as to the genital or reflex or cere[illegible] of hysteria were as animated as at [illegible] ng the term "animal spirit" for [illegible] be [illegible] *force*, supported the cerebral [illegible] and neurologist c[illegible] th [illegible] bral theory, anticipated many of the views of Brown-Séquard and Charcot. A fair idea of the views entertained by general practitioners of the eighteenth century as to hysteria may be gleaned from Smollett's description of the hysteric servant girl in "Humphrey Clinker." The girl displayed all the convulsive conditions and emotional outbursts supposed to be characteristic of the modern fine lady. This servant girl (being in Edinburgh, where the practice then, as in Chicago today, was to throw all garbage into the alleys), remarks: "A sweet savor comes from such a number of perfuming pans, but they say it is wholesome, and, truly, I believe it is, for being in the vapors and thinking of Isabel and Mr. Clinker I was going into a fit of asterisks, when this fiff, saving your presence, took me by the nose so powerfully that I sneezed three times, and found myself wonderfully refreshed, and this to be sure is the raisin why there are no fits in Hadding burrough."

The peculiar effects here ascribed to odors survive in much of the medicinal therapeusis of hysteria today. Certainly the use of musk, castoreum, assafetida and the valerianates suggests the potent effect of stimulus to the olfactory anesthesia of the hysteric.

Medicinal treatment for centuries has practically ranged along the lines of the antispasmodics. In the early sixteenth, seventeenth and even eighteenth centuries, skatologic therapeusis of the type indicated by Smollett was not an uncommon phenomenon. Of this therapeusis the *mistura diabolicum* of the first half of the present century was a sturdy survivor. Its essential ingredients of olfactory unsavoriness were added according to the taste and fancy of the prescriber and his sense of the exigencies of the case. The medicinal treatment of hysteria should be based on certain essential principles: The avoidance of excess in drugging; the avoidance of narcotics in order to prevent the formation of drug habits; discretion in the use of the bromids in order to avoid bromism and resultant debility; the careful use of cathartics that constipation with its frequent serious effects on the general, mental and nervous state of the patient may be avoided; counterirritants to protect the patient against local vasomotor results of auto-suggestion so frequent in hysteria.

For the relief of the vasomotor instability resultant in the various emotional states, zinc and other valerianates are often useful. Against this, and the erotism, camphor monobromate is frequently beneficial.

To secure slumber, whose non-existence should first be ascertained, trional, phenacetin and sulphonal, rather than chloral or morphin, should be used.

For the relief of the pseudo-anginas, glonoin or strychnin is of value. In the convulsions of grave hysteria, the hypodermic administration of apomorphia will often prove beneficial or glonoin, or the inhalation of amyl nitrite may prove equally valuable.

Hysteric aphonia and deafness have frequently been removed by amyl nitrite.

LOCAL AND GYNECOLOGIC PROCESS OF HYSTERIA.

Dr. W. H. Rumpf—Dr. Coolidge has said so much concerning the relations between hysteria and gynecologic diseases, that there is very little left for me to add. Undoubtedly, impairment of the functions or disease of the genital organs have a great influence upon the nervous system, and any derangement of these would naturally increase the neurosis that might be present. Any disease of these organs would be treated either locally or by operation according to the rules that govern us in our gynecologic work, whether hysteria is present or not. It is very essential to warn against unnecessary treatment when hysteria is present, and in many cases better results are obtained by mere suggestion and mental treatment than by actual operations.

(To be continued.)

American Public Health Association.

Twenty-fifth Annual Session Held in Philadelphia, Oct. 26-29, 1897, at the Hotel Walton.

(Concluded from page 1222.)

A BRIEF REVIEW OF THE WORK OF THE SAND FILTERS AT LAWRENCE, MASS.,

was a paper by H. W. Clark, chemist in charge of the Lawrence Experiment Station. Up to 1875, the water of the city used for all domestic purposes was obtained from ordinary wells. In that year, however, a public water supply system was constructed and the water pumped to the reservoir and distributed to the citizens from the river at a point about one mile above the city. Nine miles up the river from the intake was the city of Lowell, having at that time a population of 85,000. The sewage of Lowell was and is still discharged into the river, and above Lowell are other cities and towns also discharging their sewage into the river. This water supplied to Lowell was then, from the first, beginning to be badly polluted, but was evidently purer than the average well water previously used, as shown by a considerable decrease in the death rate following its introduction. Gradually, however, typhoid fever became more and more prevalent, and finally the death rate in the city from this disease became the highest in the State, being about three times as great per 10,000 population as the average city of the State. The cause of the epidemics which prevailed during months when other cities were comparatively free from it was the polluted water-supply, and the question of a new supply began to be agitated. In the meantime, investigations in regard to the purification of Merrimac river water by sand filtration had been carried on at the Lawrence experiment station of the State Board of Health, and had resulted so satisfactorily that as early as 1891, the city was advised to construct a sand filter large enough to filter the entire water-supply, and in 1892 the city government made an appropriation for beginning its construction under the State Board of Health. In January following the starting of the filter, the number of cases of typhoid fever was nine, or one eighth as many as during the previous January. This fact is more striking when we note that in Lowell during this month there were ninety-nine cases, or three times as many as during the previous January. In January, 1896, there were six cases; January, 1897, two cases. A more satisfactory demonstration of the effect of the filter upon the health of the people of Lawrence can be made, however, by stating that in 1887 the deaths from typhoid fever were 12 per 10,000; in 1889, 13.75 per 10,000; 1890, 13,33; in 1891, 12.20; in 1892, 11.11. During 1893 the filter was built, and hence a portion of the year filtered water was being used. In 1894, filtered water was in use during the entire year, and the death rate from this disease was five per 10,000; during 1895, it was 3.07; 1896, 1.86, and the rate for the present year promises to be exactly the same as for 1896. Besides giving a water free from disease germs, the filter is also giving a cleaner water, more attractive and palatable and containing but 50 per cent. of the organic matter of the river water.

In the evening the Association was received formally by the Mayor, and were given an opportunity to go through the public buildings, which were brilliantly lighted for that purpose.

Friday Session.

By invitation of the trustees and faculty of the University of Pennsylvania and by special permission of the students, the Association met in Houston Hall.

After the usual report of the Executive Committee, the nominations for officers for the ensuing year were announced: President, Dr. Charles A. Lindsley, New Haven, Conn., Secretary of the State Board of Health; first vice president, Dr. Benjamin Lee, Philadelphia, Secretary of the State Board of Health of Pennsylvania; second vice-president, Dr. John C. Shrader, Iowa City, Iowa; secretary to fill the unexpired term of Dr. Irving A. Watson, resigned, Dr. C. O. Probst, Columbus, Ohio, Secretary of the State Board of Health; treasurer, Dr. Henry D. Holton, Brattleboro, Vt., member of the State Board of Health. Next place of meeting, Ottawa, Canada.

Mr. Rudolph Hering, C. E., of New York. reported on "Disposal of Garbage and Refuse." He made the statement that besides the reduction of the garbage to grease and as a fertilizer, or its total destruction by cremation, there is no other process the committee can mention as commendable from an economic or sanitary point of view.

Dr. C. O. Probst of Ohio reported for the Committee on Transportation and Disposal of the Dead and favored the shipment of bodies previously prepared by a licensed embalmer, the body placed in a hermetically sealed casket. Dr. Henry Mitchell, Secretary of the State Board of Health of New Jersey, objected to this as creating a special class of workers to whom all such work would necessarily be referred. He offered a motion which was adopted, striking out licensed embalmer and inserting under the supervision of the provincial or State sanitary authorities.

Dr. Mitchell presented the report of a committee to examine and report on the existing sanitary municipal organizations of the countries belonging to the Association with a view to mention those which had been most successful in practical results.

UNIFORM AND CO-OPERATIVE HEALTH LAWS

was presented by S. P. Heilman, M.D., of Heilmandale, Pa., Medical Inspector for the County of Lebanon, Pa. He said: "I appear before you today in a dual capacity as an officer of the State Board of Health of Pennsylvania and as a member of the Farmers' National Congress. At the recent session of this

Congress held at St. Paul a resolution was adopted favoring uniform and co-operative health laws, and a committee of three appointed to further the matter of the resolution. As a system of uniform and co-operative health laws applicable to all parts of the wide domain of our United States can hardly be thought of as attainable without the pre existent establishment of a National Department of Public Health, headed by a Secretary of Health or a Commissioner of Health. Our committee assumes that that is what was really in view when the resolution favoring uniform and co operative health laws was offered and adopted. You are aware that at the last meeting of the American Medical Association, held in Philadelphia June 1 to 4, 1897, a committee was appointed to draft a bill for a Department of Public Health and to define its duties, with instructions to present said bill to the United States Congress at the next meeting of the same. Such a bill has now been drafted by that committee. This measure, if presented to the United States Congress by an Association as distinguished and learned as the American Medical Association, seconded by the Farmers' National Congress (whose part in the matter has just been explained) and reinforced by this most distinguished American Public Health Association, more largely concerned in the matter than either of the two associations named, and by far the better judge as to the necessity for a department of public health, and whose deliberate averment would be an invincible argument in favor of a department of public health, our committee respectfully submits, if presented with the recommendation of the three bodies named ought to go to the Congress of the United States with a force commensurate with the dignity, learning and influence of the bodies making the recommendation.

Some considerations on the "Hygienic Influence of Forests" by Prof. Salvador Garcialdiego, Dean of the Medical College of Guadaljara, Mexico, was read by Dr. A. L. Gihon, U. S. N., retired.

The Executive Committee, as a part of its final report, recommended favorable action on the proposition to establish a National Department of Health; this caused much discussion before its final adoption.

Dr. P. H. Bailhache, U. S. Marine Hospital-Service urged delay and held it as improper for this an International Congress to take such action for one country, concerning which the others had no right to act. Whatever we of the United States might think of it, Canada and Mexico, a part of this Association, really had no right to give any advice.

Dr. A. L. Gihon opposed this view, and argued strongly in favor of the adoption of the report of the Committee.

Dr. E. O. Shakespeare of Philadelphia, regarded this most important and action should be taken with proper consideration. The proposed bill was too long and in some places the language was ambiguous; he objected to the bill. He urged the return of the bill to the Committee for further consideration.

A vote was taken adopting the report as read, and the following resolution:

Resolved, That this Association reaffirms its urgent opinion, and petitions the Congress of the United States to organize and establish a National Department of Health, and orders a copy of this resolution to be transmitted to Congress with the report of the Committee on Health Legislation, and the accompanying papers.

THE PRESENT MORTALITY RATE IN DIPHTHERIA

was presented by I. Newton Snively, M.D., Philadelphia. He said: The American Pediatric Society made the significant statement that, in its judgment, the results from the serum treatment of diphtheria would gradually further improve. The reasons given for this statement were that, 1, antitoxin is still frequently used too late, either from procrastination on the part of the physicians or objections on the part of friends; 2, it is given in a half-hearted way and often in doses one-tenth to one-fourth as large as they should be. It has been frequently observed that the percentage of recoveries under antitoxin treatment has steadily increased from the beginning. The present mortality, the lowest ever recorded, is pronounced by most observers of large experience with the remedy, especially in private practice, as being entirely too high to represent the power of the remedy. He quoted from Holt the statement that from the most trustworthy statistics it appears that the actual mortality from diphtheria, including membranous croup, has been reduced at least one-half by the general adoption of serum treatment, and that in cases injected reasonably early the mortality is less than 5 per cent. The present mortality, all cases being included irrespective of the brand of antitoxin employed, or the day on which the serum treatment was introduced, was given as follows: General, 8 to 10 per cent.; general (antitoxin used reasonably early) 5 to 7 per cent.: laryngeal types, 21 per cent.; operative laryngeal cases, 27 per cent.; non-operative laryngeal cases, 17 per cent.; number of laryngeal cases, requiring operation, 17 per cent.

The doctor then proceeded to show upon what a further reduction in the fatality from this disease must, in his opinion, depend. He observed that a study of the vast accumulation of reliable literature on the subject shows great improvement in three distinct lines: 1. In the production of the remedy, a more concentrated and potent product being now available. 2. The treatment is introduced earlier than formerly. 3. Appreciating more and more the efficiency and harmlessness of the remedy, the physician uses larger doses and, where repetition is found necessary, waits a much shorter time.

Speaking of improvements made in the remedy he observed what is now so generally conceded, namely, that the greatest improvement yet made has been in producing a much more concentrated product. The antitoxins now available to the profession vary in potency from 50 to 500 immunizing units to each cubic centimeter of serum. The major portion of the products range in strength from 100 to 200 units per cubic centimeter of serum. The most concentrated antitoxin in common use is that known to the profession as "Extra Potent" (Mulford's), containing 500 units to each cubic centimeter.

The advantages of concentration were then minutely pointed out. Such serums disturb the tissues but little because of the small quantity to be injected, they are quickly absorbed and always produce earlier results. The advantages of concentration in producing earlier and better results were compared with those of tinctures and fluid extracts over the infusions of the older pharmacopeias. Only such products are recognized in the recommendations of the American Pediatric Society.

In the early days of antitoxin treatment it was proper to speak of obtaining results from a curative dose in from twenty-four to forty-eight hours. At present effects are expected in from twelve to eighteen hours, and are secured early in proportion to the degree of concentration of the antitoxin employed. The general employment of concentrated antitoxins of uniform quality will insure increasing success in the treatment of diphtheria and membranous croup.

The importance of care in the selection of antitoxin was then pointed out and the fact cited that examinations made by the Pennsylvania and Massachusetts State Boards of Health and the *Medical News* all show the presence in the market of serums of weak, variable and uncertain quality. The importance of eliminating such either by proper State authorities or by the careful practitioner was emphasized as essential, if the fullest powers of the remedy are to be secured.

Reverting to the hostility which some physicians still show toward the treatment, the doctor observed that the principles upon which the remedy is obtained and employed are now so firmly established both experimentally and clinically, that there would seem to be no reason why the entire profession should not accept them.

The importance of instructing the laity to report all cases of throat ailment early was emphasized and the reasons for the superior results from early antitoxin treatment pointed out.

Antitoxin must be employed as any other antidote in order to obtain the greatest possible results. At present no rule for dosage can be laid down except that the dose should always be graded to the severity of the case and that no dose of less than 1,000 units should be considered a curative dose. The importance of the initial dose as compared with any other that may be required in an individual case was clearly pointed out. Experience has explicitly shown that in severe cases one dose of 2,000 units will result in a larger percentage of cures than will three or four doses of 1,000 units each, given at intervals of from twelve to thirty-six hours. No maximum limit of dose has yet been ascertained and probably does not exist. Reports from large users of antitoxin show that at present curative doses ranging from 1,000 to 6,000 units are employed with excellent results.

The further increase in the rate of recovery from diphtheria will depend upon:

1. The production and use of only concentrated antitoxin.
2. The elimination from our market of all serums of variable, weak and uncertain quality, no serum of less than 200 units per cubit centimeter being accepted.
3. The general employment of approved serum, according to the best teaching of the profession.
4. By treating each case of the disease as speedily as possible, aiming to neutralize the abso[illegible] [illegible] [illegible]xins and arrest the disease.
5. By treating the [illegible] sease in th[illegible] way, namely, by [illegible]
6. By guarding [illegible] due [illegible] psychic and physica

7. By endeavoring, as physician, to maintain a reliable mental equipoise.

A vote of thanks was passed for the hospitality shown the members by the city authorities, the entertainments by the ladies and the pleasant entertainments by the Committee of Arrangements, etc. The officers elect were then installed.

On Saturday those who had not left the city were taken down the Delaware River to visit the State quarantine station at Marcus Hook, where they were provided with a luncheon, thence to Reedy Island, where the disinfecting plant of the Marine Hospital Service was exhibited and explained, returning to New Castle, Del., where a special train was in waiting by courtesy of the Pennsylvania Railroad, which carried the party back to the City.

NEW INSTRUMENTS.

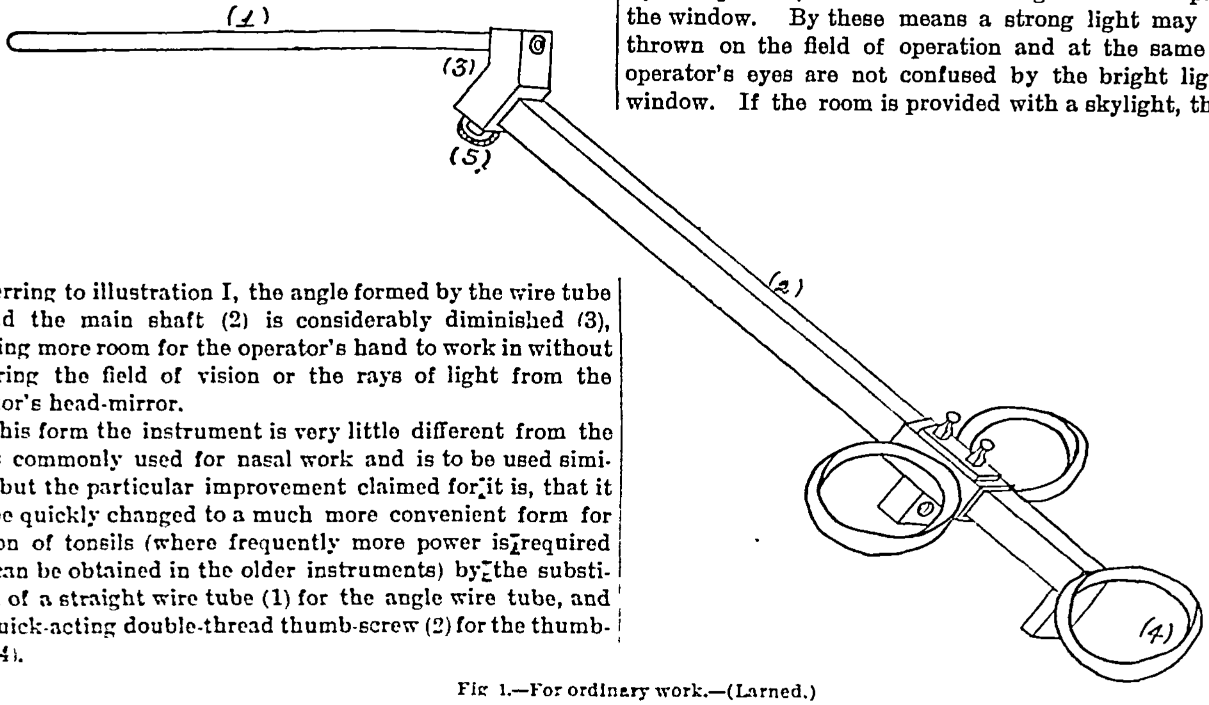
EXCISION OF THE TONSILS FOR HYPERTROPHY WITH RECURRING TONSILLITIS.

A MODIFIED INSTRUMENT AND THE TECHNIQUE OF ITS USE.

Read by Invitation at the Meeting of the Will County Medical Society, Nov. 23, 1897.

BY E. R. LARNED, M.D.
Member Chicago Medical Society, Will County Medical Society, American Medical Association, Etc.; Lecturer to Silver Cross Hospital Training School.
JOLIET, ILL.

Excision of the tonsils in cases of hypertrophy, with frequently recurring attacks of tonsillitis, promises more for the patient's immediate relief, and affords a more certain cure, than partially removing the glands; and to facilitate this procedure I have devised a modification of the Ingals' or Bosworth cold wire snare, which has proven so satisfactory as to merit a description.



Referring to illustration I, the angle formed by the wire tube (1) and the main shaft (2) is considerably diminished (3), affording more room for the operator's hand to work in without obscuring the field of vision or the rays of light from the operator's head-mirror.

In this form the instrument is very little different from the snares commonly used for nasal work and is to be used similarly, but the particular improvement claimed for it is, that it may be quickly changed to a much more convenient form for excision of tonsils (where frequently more power is required than can be obtained in the older instruments) by the substitution of a straight wire tube (1) for the angle wire tube, and of a quick-acting double-thread thumb-screw (2) for the thumb-ring (4).

Fig 1.—For ordinary work.—(Larned.)

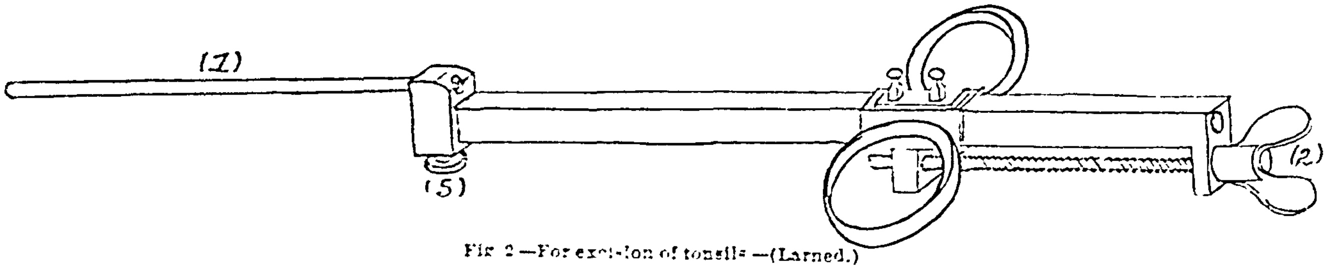


Fig 2.—For excision of tonsils.—(Larned.)

That this may be done, the wire tubes have been made interchangeable and held in place by a small set screw (5) and a place provided for the thumb ring to be screwed into the shaft. This changes the appearance of the instrument completely, as will be seen from illustration II.

The points embodied in this form of snare to which I wish to call especial attention are: *a*, The whole tensile strength of the wire is utilized instead of losing a good percentage of it by the friction at the proximal opening of the wire tube; *b*, the thumb-screw, with its double thread, acts quicker, easier and with more power than the milled nut used on the Ingals' snare. With this instrument complete excision of the tonsils can be made in only a little longer time than when using the ordinary tonsillotome.

The operation which this instrument was designed to facilitate is as follows: The patient complaining of attacks of quinsy each time a cold is contracted, is found upon examination to have hypertrophied tonsils.

This is a case where the ordinary partial removal would prove inadequate, if not actually adding to the patient's susceptibility to the recurring attacks of tonsillitis; nor would cauterization of the tonsillar crypts be of so much benefit. Frequently in these cases the tonsils are covered by the anterior pillars of the fauces and possibly this fact explains the frequent failure of tonsillotomy to permanently relieve the patient.

It is highly important that the field of operation be properly illuminated, and care be taken to select a room brightly lighted by a large window or a skylight, in which to conduct the operation. The patient is placed on a table parallel to and in front of the window. Back of the table a good-sized common mirror is placed, or held by an assistant, in such a manner that the light from the window is reflected to the head-mirror worn by the operator, who should be sitting between the patient and the window. By these means a strong light may be easily thrown on the field of operation and at the same time the operator's eyes are not confused by the bright light of the window. If the room is provided with a skylight, the light is reflected in the same manner, by holding the large mirror at the necessary angle to reflect the rays from the skylight to the operator's head-mirror.

If neither window nor skylight is available, a common "bull's eye" lantern, or a bicycle lamp, can be made to answer very well, if a regular laryngoscope is not at hand.

The operation should always be conducted with the patient thoroughly under the influence of a general anesthetic, chloroform being preferred for obvious reasons.

The posture of the patient is very important. After the patient is thoroughly anesthetized, a Waxham gag should be used to keep the jaws well apart, and held by the anesthetizer; he is then turned upon his abdomen, the face projecting over the side edge of the table (not the end), about half way, the head and uppermost arm being held by an assistant.

If, as is usually the case, the tonsil is more or less covered by the anterior pillar of the fauces, it must be separated from its covering by passing a blunt hook between it and the pillar.

The undermost tonsil is now seized with a forceps, preferably one made for this purpose, or a bullet forceps, or even ordinary hemostatic forceps, and the wire loop of the *ecraseur* passed over the locked handles of the forceps, being careful to have it encircle the gland completely; then steadily turning the thumb-screw will completely remove the tonsil, frequently without the loss of a drop of blood.

Turning the patient with his face to the other side of the table and then turning the table so that the patient faces the operator again, the remaining gland, which is now undermost, is quickly removed.

The entire operation can be carefully done in from ten to fifteen minutes, not counting the time used in anesthetizing the patient. There is no danger from hemorrhage and the tonsillitis can not recur.

The after-treatment should consist of gargling once an hour, except during sleep, for two or three days following the operation, with rather warm water containing five drops each of carbolic acid and oil of gaultheria to the ounce.

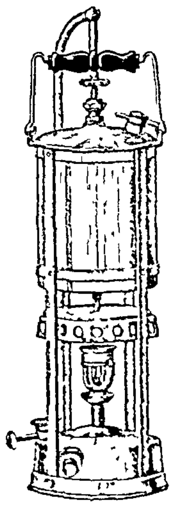
A careful observation of the many little points of technique in this description makes the operation neat and satisfactory to the patient's friends and the operator.

The snare has comparatively few parts and may be thoroughly sterilized by boiling. The instrument and sketches are the product of my leisure moments, but any instrument maker can manufacture the snare by reference to the drawings.

426 Barber Bldg.

APARTMENT DISINFECTION.

The value of formic aldehyde gas in disinfecting is now generally recognized, but there have been many difficulties attending its efficient application. The volume used must be amply large and liberated with sufficient rapidity to overcome all the disadvantages. Dry heated gas is of highest value because it is most penetrating and, having a specific gravity equal to that of atmospheric air, mixes freely with air, thus producing it effects wherever air can penetrate.



In an effort to secure the best effects the following simpl apparatus (shown in the illustration) has been devised. I consists of a Swiss heating lamp beneath a reservoir for com mercial formaldehyde. Between these is a copper coil open ing into the receiver and ending in a short gum hose, at the dis tal end of which is a thin feeding-tube. The opening from th reservoir into the tube is protected by a valve. When the tub is red-hot, the valve is opened to admit a small stream of solu tion of formaldehyde. This is instantly vaporized aud the lib erated gas and vapor intensely heated as it passes through th coil. The gas is not liberated under pressure, hence there ca be no danger from inflammation or explosion. By means o the feeding-tube, an apartment is filled with gas through a key hole or other suitable opening.

The apparatus is always on the outside of the apartment be ing disinfected, and is capable of filling an ordinary room with in half an hour, so that one operator can easily disinfect a many as two dozen rooms per day, if not too remote one fro the other. The apparatus can be obtained of H. K. Mulford Co., Philadelphia.

SELECTIONS.

The "Carlsbad Springs" of the United States of North Americ — . . . The United States excels all other countries of th globe in the number and varying character of its minera springs. . . . In the Thirty second bulletin of the United States Geological Survey (1886) there is an elaborate, and a far as possible, exhaustive report, prepared by Albert C. Peale, M.D., in which there are mentioned 2,822 localities, containing 8,822 distinct springs. Of the latter but 634 have been quantitatively analyzed, and 153 tested simply for the nature of thei ingredients (qualitatively analyzed). Of these, 223 were being used commercially in 1896, 17 having been added to this number in 1890, which is the date of the last general report on th subject.

The figures as above given, incomplete as they are, demonstrate that while the number of springs which have been analyzed is less than a quarter of those of Europe, the sum total of those in the United States largely outnumbers those of that continent, as enumerated by Dr. Friedrich Raspe in his "Heilquellen Analysen." This author gives between 2,800 and 2,900 analyses of as many different springs situated in various parts of the continent of Europe. This great disparity is obviously due to the older civilization of Europe, and the greater facility and cheapness with which analyses are obtained there. Among the springs of our own country, with whose composition we are acquainted, and which, in spite of our youth, have been fully tested as to their intrinsic qualities as health restorers, there are a great many which may fearlessly take up the gauntlet and challenge the most celebrated health resorts of the Old World as to their value and efficacy in this direction. If Americans prefer European spas to the springs of their own land, it is doubtless due to their desire to travel "over the sea," the benefits of a voyage, or to lack of acquaintance with the resources of our country.

Among the oldest and most celebrated mineral springs and health resorts of Europe Carlsbad claims a prominent place, a claim readily granted by balneologic authors, as its springs have enjoyed for centuries a deservedly high reputation as a "resort for invalids and not for pleasure." . . . The hot waters here issue forth from a subterranean basin whose nature and contents have been plainly elucidated by Berzelius, who demonstrated "that the incrustations produced by the decomposi[illegible] n contact with [illegible] phere has formed a [illegible] the wate[illegible] themselves to the surface, at a temperature higher or lower according to the distance they had to travel beneath the shell before finding exit." There are quite a number of springs differing from each other mainly in the temperature at which they emerge from the earth, the range being from 115 to 162 degrees, with but slight variation in the nature or quantity of their solid contents. It will be sufficient, therefore, to mention the analysis of the most prominent, the "Sprudel," one gallon (58,329 grains) of which contains 326 grains of solid ingredients as follow: Calcium carbonate, 18.012; ferrous carbonate, .205: lithium carbonate, .152; magnesium carbonate, 10.404; manganous carbonate, .045; sodium carbonate, 77.003; strontium carbonate, .053; sodium phosphate, .028; potassium sulphate, 8.446; sodium sulphate, 146.558; sodium bromid, .015; sodium chlorid, 60.610; sodium iodid, .001; calcium fluorid, .186; alumina, .129; silica, 4.385. Total, 326.232 grs.

There are no less than eight known mineral springs in the United States for which the term "Carlsbad" is chosen to at once demonstrate their superior efficiency. . . .

"*America's Carlsbad,*" *the Bowden Lithia Springs*, are situated among the granite hills of Northern Georgia, four miles west of Atlanta, at an altitude of 1,200 feet above the sea, with a mild and dry climate, whose temperature "rarely reaches 90 degrees in summer or goes below 40 degrees in winter." There are several springs on the grounds, which are encased, and used only partly for drinking purposes. The rest of their waters are pumped into a reservoir, from which the bath-house is supplied. "For the company has secured a competent physician, who is familiar with Hot Springs, Ark., to introduce the famous Hot Springs system of bathing at Lithia Springs." There are other arrangements for the comfort and benefit of the guests. A great stress is laid upon the presence of lithia in the water, and on this account it is most strenuously recommended as the water which "has been proven to be nature's remedy for rheumatism, bladder and kidney diseases." . . . A United States gallon of the Bowden Springs water contains 138 grains of solid ingredients, as follow: Calcium bicarbonate, 14.372; ferrous bicarbonate, .179; lithium bicarbonate, 3.706; magnesium bicarbonate, 2.395; aluminum sulphate, .442; calcium sulphate, 10.127; potassium sulphate, 1.221; sodium sulphate, .693; strontium sulphate, 1.013; sodium chlorid, 101.482; magnesium chlorid, 1.442; silica, 1.052. It is plainly observed that chlorid of sodium is the predominating substance in this analysis, and a water holding as small an amount of alkalies among its solid ingredients can not be classified with an "alkaline-saline purgative water" like Carlsbad; it is a *saline water*. It appears now that neither the constituents of the springs nor the temperature of their waters bear any resemblance to the springs whose title has been assumed, but as it can not be presumed that the assumption has been wanton and without any cause, it may be surmised that the therapeutic effects from both have been such as to justify the Bowden Springs taking to themselves the name of the older, renowned watering-place.

The "*West Baden Mineral Springs*, the 'Carlsbad' of America" . . . are located on a tract of land nearly 700 acres in extent, where they are "surrounded by a series of majestic hills, under whose beautiful groves of noble forest trees the walks and grounds are sheltered." There are seven springs announced, which yield from 30 to 120 gallons per minute, and "this quantity is not perceptibly increased or diminished during the longest spells of wet or dry weather." It has a uniform temperature of 53 degrees F. during summer and winter, and "the quantity and temperature being uniform under all circumstances, gives a confidence, which experience in its use has verified, of its uniform strength and efficacy." . . . Although there are seven springs mentioned, the analyses of but four have been published, Nos. 1, 3, 5 and 7, of which the latter two have the largest amount of solid ingredients, 351 and 372 grains in one gallon, respectively. No 1 contains about 283 grains of solid matter. Below you find the analysis, by E. T. Cox, State Geologist, of No. 7, the largest spring in the valley. It contains, in one United States gallon, the following substances in grains: Calcium carbonate, 31.487; ferrous carbonate, 2.915; magnesium carbonate, 32.784; potassium carbonate, .655; sodium carbonate, 9.687; aluminum sulphate, 2.573; calcium sulphate, 86.011; magnesium sulphate, 13.798; potassium sulphate, .843; sodium sulphate, 28.857; calcium chlorid, 7.851; magnesium chlorid, 13.102; sodium chlorid, [illegible]; total, 371.84 grs. The gaseous contents in one gallon, in cubic inches: Carbonic acid, [illegible]; nitric acid, 18.274; sulphuric acid, 4.205; oxygen, 6.147; sulphur. hydrogen, 9.987. According to this evidence, the water must be classed among the calcic waters with alkaline-saline properties, and should therefore be considered favorably in its comparison with Carlsbad water.

The "*American Carlsbad Springs*" are located at Nashville, Ill., . . . in altitude about 100 feet above St. Louis and 500 feet above the level of the sea. These so-called springs are actually artesian wells, which "after being bored yielded saline water in considerable abundance to warrant their commercial use." . . The temperature of the water is 65 degrees F. It has been analyzed by Dr. Chas. Ludeking of St. Louis and W. F. Hillebrand of the United States Geological Survey, and contains in one United States gallon 260 grains of the following mineral substances: Sodium chlorid, 10.0; sodium carbonate, 27.4; calcium sulphate, 65.8; magnesium sulphate, 103.7 sodium sulphate, 53.0. This analysis places the water in the class of purgative waters, allied to the Carlsbad by its sodium salts. . . .

"*The Colorado Carlsbad Mineral Water Springs*" are located four miles east of Barr, a station on the B. & M. R.R., eighteen miles from Denver. . . . Two analyses have been made of the water, which differ from each other by about 5 per cent., and also in the arrangement of the probable constituents; one is by Prof. S. A. Lattimore of Rochester, N.Y., and the other by Prof. Karl Langenbeck of Cincinnati. S. A. Lattimore found in one United States gallon, 111.2 grains: Calcium carbonate, 2.144 grains; calcium sulphate, 26.429 grains; magnesium sulphate, 10.764 grains; sodium sulphate, 61.108 grains; sodium chlorid, 10.734 grains. Karl Langenbeck found in one United States gallon, 116.8 grains: Calcium carbonate, 18.657 grains; magnesium carbonate, 3.393 grains; sodium carbonate, 2.318 grains; sodium sulphate, 82.984 grains; sodium chlorid, 9.476 grains. Traces of substances can not be taken into consideration.

Both of the analysts have accompanied their reports with statements of the therapeutic value of the water, and while Professor Lattimore satisfies himself with declaring that it "bears in its composition a striking resemblance to the well-known Carlsbad water of Bohemia," Professor Langenbeck is more enthusiastic and positive in calling it "a water exactly of the Carlsbad and Franzensbrunnen type, although about one-third the strength of these." In their comparison of the Colorado spring they have neglected entirely one and the most important factors, to-wit: the temperature.

"*Hot Springs, S. D., in the famous Black Hills.*"—Its principal ingredients are the sulphates of calcium, sodium and potassium, together 65 grains, while the balance is divided among some other calcium and magnesium salts.

The "*Las Vegas Hot Springs*" are situated about six miles from the old town of Las Vegas, N. M., at an altitude of 6,767 feet, where "some forty springs bubble out of the hillside, varying in temperature from ice cold to boiling hot, but most of them ranging from 110 to 144 degrees F." The analyses of some twenty odd of these springs were made as early as January, 1882, when the water was collected and the temperatures taken by Prof. J. T. Lovewell, Washburn College, Topeka, Kan. He determined the carbonates of calcium and sodium, sodium sulphate, sodium chlorid and silicic acid, and mentions small quantities of magnesium and potassium and traces of lithium. Like in other localities where a number of hot springs are found to issue, the individual springs differ mainly in their temperature, but not very much in their solid constituents, which in this case, vary a fraction of a grain only in 10,000 parts, while the sum total of each of the twenty odd springs as mentioned above amounts to an average of 33 grains in a United States gallon.

A small, neat pamphlet entitled "The Land of Sunshine" mentions the analysis of one spring made by Walter S. Haines, M.D., Professor of Chemistry, Rush Medical College, in 1895, which is here selected as a sample, because it exhibits more details of the solid ingredients, and allows a more easy comparison with other known analyses. The following are the solid contents of one gallon in grains: Calcium carbonate, .89 grains; magnesium carbonate, .15; potassium carbonate, .28; sodium carbonate, 8.38; sodium sulphate, 3.35; sodium chlorid, 14.68; silica, 3.50; alumina, .10; volatile and organic matter, .32. Total, 31.65 grains. In the remarks which accompany his report, Dr. Haines states "that in many respects the springs resemble in chemic composition the waters of the famous ones of Teplitz and Carlsbad," which is correct, when we take into consideration only the relative proportion of the ingredients to each other, but when we compare the quantities of solids of the two different localities, we find that the Carlsbad springs contain about ten *times* as much solid matter as the Las Vegas springs. Otherwise there is really a great resemblance between the analyses of the two waters, and in the light of the recently advocated doctrine of flooding and washing out the system, the Las Vegas as ten times the weaker might be taken for ten times the superior. While the springs are surely the principal attraction of Las Vegas, there are other prominent features which ought to make it a decidedly delightful health resort. Its high elevation, its dry and uniform climate and its situation on a large tract of land which is surrounded by high hills that form almost a complete circle and protect the valley against the cold north winds, and especially the sand storms, the plague of these regions. The mean annual temperature is 59.07 degrees F.; during the summer it rarely rises above 90 degrees F. The rainfall is less than one inch during the same time, and about twelve inches during the whole year with an average number of 326 sunny days. The nights are always cool and a blanket comfortable even in summer. The Hot Springs of Arkansas also aspire to be classed among the competitors of Carlsbad. . . They are situated in 34 degrees 31 minutes N. latitude and 92 degrees 31 minutes W. longitude, at an elevation of 600 feet above the Gulf of Mexico. The climate is clear and beautiful, while the temperature rarely reaches an extreme in either direction, to render it uncomfortable. The sun passes down behind the west mountain early in the evening, giving a delightful long twilight and always insuring cool nights in summer. Its annual mean temperature is 76.67 degrees with lowest mean in January, 55.32 degrees, and highest in July, 95.48 degrees F. There are in all seventy-three springs which are discharged at a temperature from 77 to 157 degrees F. All of them have been neatly encased and their waters collected in one large reservoir, from which the hotels and the bath-houses are supplied with a daily output of 840,000 gallons. The water like that of many thermal springs carries in solution but a small quantity of solid ingredients. Prof. E. H. Larkin, in 1856, found eight and one-half grains to a gallon of water, which is still maintained as correct. He determined the proportion of its constituents, of which lime, silica and carbonic acid formed over 75 per cent. in almost equal quantities, the balance being alumina, iron, magnesia, soda, potash, chlorin and sulphuric acid to the amount of 15 per cent., and water and organic matter 10 per cent. It is obvious that if the quantity of solid constituents would decide the efficiency of a thermal spring, Hot Springs could not come into competition with Carlsbad and its 323 grains of solids in a gallon or about forty times the quantity of mineral ingredients. In all thermal waters, however, the natural high temperature is of the foremost importance, and should therefore be taken first into consideration. Thousands of sufferers stake their faith on Hot Springs every year, and have been rewarded for their confidence by being restored to health and activity. And it should always be remembered that if the high temperature be assisted by an almost absolutely pure water, its cleansing effect, whether it be employed for external or internal purposes, would be of the most intense quality. And if the dispensation of other medicines should be decided on, a purer menstruum could not be selected for their administration and even an artificial Carlsbad easily be prepared by the addition of the requisite substances. There is no doubt that the Hot Springs of Arkansas have the right to call themselves the "Carlsbad of America." *The Paraiso Hot Springs* are situated in California, 150 miles south of San Francisco, at an elevation of about 1,200 feet above the level of the sea, and nearly 1,000 feet above the valley. The temperature of the water is 118 degrees F., and the chief of its ingredients is sodium sulphate, although in decidedly less quantity than it occurs in the Carlsbad springs. However, a comparison of the analyses of the two springs makes it plain that there is a great similarity in the proportions of the active elements, and, therefore, we shall not antagonize the opinion of W. Anderson, M.D.: "This water is found to be very similar to the noted Carlsbad of Austria." According to his careful chemic analysis the water contains 61.45 grains in one U. S. gallon of the following mineral ingredients: Calcium carbonate, 1.30 grains; ferrous carbonate, .89; Magnesium, carbonate, .75; sodium carbonate, 5.06; calcium sulphate, 6.45; magnesium sulphate, 1.10; potassium sulphate, a trace; sodium sulphate 34.60; sodium chlorid, 3.37; potassium chlorid, .32; aluminum chlorid, .56; silica chlorid, 2.90; organic matter, 4.15. Total solids. 61.45.—Abstract of a paper by Enno Sander, M.D., in the *Medical Mirror.*

How We Feel When We Die.—In the *Review of Reviews* for September, 1892, is to be found an article bearing upon the above rather startling title, which is thus introduced to the readers of the magazine by its editor: "The July number of the 'Proceedings of the Society of Psychical Research' contains a paper of surpassing interest by Mr. T. W. H. Myers, . . . As it is appointed to all men to die, and as in the whole range of human literature there are hardly any authentic narratives as to how a man feels at the moment of death, the evidence in this paper is extremely interesting. Of the two narratives Mr. Myers gives us, the first is the most remarkable, although they are both exceedingly wonderful. The first was contributed by Dr. Wiltse of the *St. Louis Medical and Surgical Journal.* Dr. Wiltse is the authority for the statements which follow. . . . The second story is of a Huguenot minister, Bertrand by name. It is not so recent, but it is quite as remarkable in its way." Then follow the stories, which I shall give as briefly as possible, but verbatim. To begin with Dr. Wiltse's narrative: Dr. Wiltse "appeared to come to the moment of death in the last stage of typhus fever." He thus describes his experience: "I said to myself, 'I have died as men term death; I am about to get out of the body,' and I watched the interesting process of the separation of soul and body. By some power apparently not my own, the ego was rocked to and fro laterally, by which process its connection with the tissues was broken up. After a little time the lateral motion ceased and along the soles of the feet I felt and heard, as it seemed the snapping of innumerable small cords, when this was accomplished I began slowly to retreat from the feet toward the head. I remember saying to myself, 'now there is no life beyond the hips'; then, 'I am all in the head now and shall soon be free.' As I emerged from the head I distinctly recollect how I appeared to myself, something like a jelly-fish as regards form and color. I floated up and down like a soap bubble, until I broke loose from the body and fell lightly to the floor, where I slowly arose and expanded into the full stature of man. I seemed to be translucent and of a bluish color; as I neared the door I found myself clothed. I examined the fabric and judged it to be some kind of Scotch material, not handsome, I thought, but neat and good enough. . . . I discovered that a cord like the thread of a spider's web ran from my shoulders back to my old body, and was attached to it at the base of the neck. I stood and gazed at the couch I had just left and saw my own dead body. I noticed two women kneeling be my side, but had no conception of individuality; wife, sister or friend were as one to me. I could distinguish sex, but nothing further." He left the house and went out into the street, then he rose into the air, "upheld by a pair of hands," till he arrived at a narrow roadway, along which he walked for a while. At last he came to three great rocks barring the way, "and a voice spoke to him out of a cloud: 'Once you pass them you can no more return to the body.'" He desired to pass, but was stopped. He "became unconscious again, and when he awoke he was lying on his bed. He awoke to consciousness and soon recovered."

So much for the first story, now for the second. Pastor Bertrand was climbing a mountain with a party of students; feeling tired, he lay down to rest while the others proceeded, and was overtaken by "the sleep of the snow." He felt himself as if struck by apoplexy. His head was perfectly clear, but his body was powerless. He tells his story thus: "A kind of prayer was sent up, and then I resolved to study quietly the progress of death. . . . The sensation was not painful, but at last my head became unbearably cold, and it seemed to me that concave pincers squeezed my heart so as to extract my life. I never felt such pain, but it lasted only a minute and my life went out. 'Well,' thought I, 'I am what they call a dead man, and here I am, a captive balloon, attached to the earth by a kind of elastic string, and going up, and always up.' . . . When my companions return they will say, 'The Professor's dead!' They do not know I never was as alive as I am! The proof is, I see them now; the guide is stealing a leg of my chicken. 'Go on, old fellow, eat the whole if you choose, for I hope my corpse will never eat again! Hello, there is my wife going to Lucerne. Well, wife, good-bye!' I confess I did not call *dear* the one who has always been *very dear* to me. I felt neither regret nor joy at leaving her. My only regret was that I could not cut the string Suddenly a shock stopped my ascension, I felt [illegible] ing the balloon down. My grief was [illegible] ched [illegible] I had a last hope, the [illegible] Suddenly I uttered the awful roar of a wild beast; the corpse swallowed the balloon and Bertrand was Bertrand again!" In other words, the exertions of his friends were successful in resuscitating him.

So much for the stories themselves, now for the comments of the *Review of Reviews:* "Both of these stories," it tells us, "agree in the consciousness of the apparently dead person that he exists apart from the body with which he was connected by a very fine line, the severance of which would complete the process of dying. . . . The moral of both seems to be that what we call dying is no more death than the changing of a suit of clothes is dying. . . . The ugly part of both stories is the comparative indifference with which the liberated soul regarded those whom it loved on earth. This, however, is so contrary both to experience and to reason, that it may be regarded as exceptional and due solely to the novelty of the situation, which in these cases had no time to pass before the process of dying was rudely interrupted."

Now I would ask: What "experience" is here meant? Not the ordinary experience of the living, surely, for that is quite beside the mark? And if, as the *Review of Reviews* tells us, the significance and importance of these narratives lie in their being almost the *only* revelations we have of the condition of the soul *after* leaving the body, it seems hardly consistent to accept the statements of the narrators as authoritative on some points, yet attempt to explain them away on others. Why, for example, should we be willing to believe on Dr. Wiltse's authority that the soul as it first emerges from the brain is "of the color and consistency of a jelly-fish," yet refuse to belive, on the same authority, that it no longer loves or even recognizes those dear to it in life? more especially, as this loss of natural affection is testified to by both of our witnesses. Indeed, this fact and the existence of some kind of elastic connecting cord between the almost liberated soul and its cast off body, are the only two points in which their experiences are identical. As regards the character of these revelations, they are as singularly devoid of dignity and weight as the "revelations" vouchsafed by so-called "spirits" at a "séance." The idea of a "disembodied soul" keeping watch upon a thievish guide in his appropriation of a chicken-leg certainly strikes one with a sense of incongruity, while the conception of such a soul habited in "a suit of some Scotch material" is so grotesque that the gruesomeness of the situation is altogether lost sight of in its absurdity! Indeed, there is a purely mundane tone about these experiences throughout, which stamps them as being emphatically "of the earth earthy."

The absolute accuracy of the stories, so far as they relate what the narrators believe to be their actual experiences, I shall not call in question; taking it for granted that they have been thoroughly sifted and authenticated before being presented as "facts" to the readers of the *Review of Reviews*. [illegible] must, however, express my surprise at the importance attached to them by that periodical. To me, they appear to belong precisely to the same category as those wonderful experiences related by patients who have recovered from a cataleptic trance, or to the stories told by drowning persons. They [illegible] undoubtedly very curious and exceedingly interesting, as, from the nature of the case, evidence of the sort must always be most difficult to secure, for even in those cases where disease has left the mind unimpaired, death is in most instances preceded by unconsciousness. Were it possible to collect sufficient data on the subject, the physiologist might be enabled to trace the underlying law governing the physical phenomena of death, and discover that certain differences of sensation mark the approach of death in different forms. Such knowledge, from a scientific point of view, would of course be most interesting. Had the article in question borne the title: "How we feel when we come as near death as we can come *without* dying," it would exactly have described the subject-matter; but its actual title "How we feel *when* we die," is, I maintain, a misnomer. Still, as I have said, these experiences are of value (always supposing them to be well-authenticated facts), but I utterly fail to see their importance as bearing upon the elucidation of the problem of "death." For death, as I understand it, is the absolute extinction of animal life; the utter and complete severance of the bond between the material and the immaterial parts of the nature. So long as one spark of vitality remains, so long as the potentiality of life exists, it is not death, but only a more or less near approach *to* death. And the nearest approach to death is not death. The *consummation* of the act of dying *alone* is death! Hence it is that, so far as penetrating the mystery of death is concerned, these "experiences," with all their interest, leave us precisely where they find us—profoundly in the dark!—Abstract from *Review of Reviews*, by H. E. Burr.

PRACTICAL NOTES.

Etiology of Catarrh of the Upper Air-passages.—A writer in a Russian exchange mentions the universality of this affection, and emphasizes the resulting evils, especially in the young. He ascribes it largely to the fact that the mucous membranes are not supplied with the moisture required to keep them in normal activity, as soon as the weather compels us to heat our houses. The air is heated to a point when it would hold considerable moisture normally, but the little moisture in the cold outer air is dried out of it by the time it reaches our nostrils indoors.—*St. Pet. Med. Woch.*, October 23.

The Milk Diet in Kidney Lesions.—Dr. Ajello (*Blätter für Klinische Hydro-Therapie*) as quoted by the *Philadelphia Medical and Surgical Reporter*, does not believe that the milk diet is best for kidney lesion patients, but that, on the contrary, a "mixed" diet answers a better purpose in general. In his twenty-one cases he noted an increase in the quantity of urine in nine that were kept on a milk diet and eleven on a mixed diet. The albumin decreased in five cases and increased (quite considerably in some) in sixteen cases kept on milk. The urates diminished in ten milk cases, a rather unfavorable phenomenon. The phosphates diminished in seven kept on milk and thirteen on mixed diet.

The Action of X-Rays on Micro-organisms.—Bonomo and Gros have made researches in the military hospitals at Rome on this subject. They subjected cultures of various micro-organisms (B. subtilis, B. tuberculosis, B. anthracis and others) up to the third generation to the influence of the X-rays, applied vertically, for a period of about three hours each day. Some retardation or diminution of vitality, vegetative and pathogenic, was observed in every case; but the change was for the most part very slight except in the case of B. anthracis. With this microbe a well-marked diminution in motor activity, modification of chromogenic power and loss of spore-producing property was observed. With this, too, a complete attenuation of pathogenic effects was observed, so that the authors feel it might be possible through successful cultures exposed to the X-rays to make the B. anthracis innocuous. No such marked results were obtained with the other micro-organisms under the influence of the same rays. In every case such effects as were observed were more noticeable in the later than in the earlier cultures.—*British Medical Journal.*

A Pipe-stem Impacted in a Bronchus for Three Months.—The tolerance of the bronchi for large foreign bodies is well exemplified by the report by Francis (*British Medical Journal*, Sept. 25, 1897, p. 809) of a case in which a portion of pipe stem was impacted in the left bronchus for a space of three months. The patient was an army pensioner, who related that about a month before coming under observation, while standing quietly on the street smoking a briar pipe with a vulcanite stem, he was seized with a fainting fit and fell. On being raised from the ground by bystanders and recovering consciousness, he looked about for his pipe, but found that the shank was broken about an inch from the mouthpiece. The broken fragment could not be found and the man proceeded home, feeling little the worse for his accident. From this date he complained of pain more or less severe in the left breast with dyspnea on exertion and profuse mucopurulent expectoration. On examination there were heard a light systolic murmur and loud rhonchi all over the chest, which was hyperresonant. A belladonna plaster and a stimulating expectorating mixture were prescribed. A short time afterward, while carrying a heavy weight about a hundred yards in a stooping posture, the man suddenly felt something move inside his chest and following a fit of coughing the long lost pipe-shank dropped out of his mouth to the ground surrounded by a little coagulated blood and inspissated mucus, with immediate relief from the previous embarrassment of breathing. The piece of pipe-shank measured one and one-fourth by one-half inch, and must have been lodged low down in the left bronchus.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, 100 Washington St., Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the *Editor*, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

SATURDAY, DECEMBER 18, 1897.

THE FREQUENCY OF DIABETES MELLITUS, AND ITS RELATION TO DISEASES OF THE PANCREAS.

There are a number of features in connection with the general frequency of diabetes mellitus, as well as with its occurrence in certain races and in certain classes that merit particular attention. Thus, for instance, it appears that the general frequency of this disease is steadily increasing, both in the United States and in the European countries, although the disease is as yet, at any rate, much less prevalent here than across the Atlantic.

The statistics of SAUNDBY[1] show that the mortality in the United States in 1870 was 2.1 to the one hundred thousand population; whereas in 1890 the death rate was 3.8 per hundred thousand. Now, these statistics show that diabetes in this country is gradually on the increase.

HARE,[2] in recently published statistics, also demonstrates that the frequency is on the increase. He points out that in thirty years, from 1850 to 1880, the mortality from diabetes in this country increased 150 per cent. in every hundred thousand deaths.

In Europe the mortality ranges between 5 and 9 to the hundred thousand. In the Island of Malta, where the mortality from diabetes is extraordinarily high, the census of 1891 showed a death rate of 13.1 to the hundred thousand. In Paris the death rate is gradually increasing during the last three or four decades, and in 1891 it reached 14 to the hundred thousand.

In the Johns Hopkins Hospital of Baltimore there have been treated, according to THOMAS B. FUTCHER,[3] in all sixty-nine cases of diabetes mellitus, in the ordinary acceptance of the term in the medical wards and the medical section of the dispensary during the last eight years. During these eight years 45,636 medical cases have passed through the wards and the out-patient department, so that the diabetic cases comprise only .15 per cent. of all the medical cases.

It is well known that some races are especially liable to diabetes. Hebrews are especially susceptible, one-fourth of FRERICHS's cases being of the Semitic race. It is rare in negroes and Africans, and the Mongolian races are rarely affected in their own countries. Chinese are comparatively exempt. In the colored races the disease is apparently rare; TYSON[4] has seen several cases, and of the sixty-nine cases of diabetes treated in the Johns Hopkins Hospital five were negroes.

The prevalent belief that persons living in the country are more exempt from diabetes than inhabitants of cities can not be traced back to any definite statistics; on the other hand, SAUNDBY[1] shows that for many of the counties of England this discrepancy does not exist.

The above statements, taken for the most part from FUTCHER's article, indicate that the distribution of diabetes is very unequal. The same is also observed with reference to its occurrence among the various classes of people; thus wealth and culture are said to increase the liability to diabetes ten-fold. Statistics for London and Berlin show that the number of cases in the upper ten thousand exceeds the number of cases in the lower hundred thousand inhabitants. The same occurs in India, where the disease is much more frequent in the educated upper class than in the ignorant lower class.

In recent years great interest has been created in the part played by the pancreas in the causation of diabetes. For more than a century, however, it has been recognized that lesions of the pancreas may cause diabetes. In 1788 CAWLEY[5] reported a case in which the pancreas was atrophic and contained calculi, but it was not until 1877 that LANCEREAUX[5] described a special form of diabetes under the name of *diabète pancréatique*, associated with lesions of the pancreas. He stated that this variety was characterized by suddeness of onset, unusual malignancy and rapidly progressing emaciation, and a special tendency toward tuberculosis of the lungs as a complication. BAUMEL.[5] in 1882, advanced the view that all the cases of diabetes were due to the absence of a diastatic pancreatic ferment in the intestine, and he was the first to claim that pancreatic disease was the regular cause of diabetes. These observations seemed to leave no lasting impression until the discovery by MINKOWSKI and VON MERING that permanent diabetes mellitus could be produced experimentally in animals by complete removal of the pancreas, and it is now generally recognized that diseases of the pancreas are responsible for a certain number of cases of diabetes. There are some who claim that all cases of diabetes are due to pancreatic disease, maintaining that where there are no structural lesions, gross or minute, then there exists a functional disturbance of the gland; but there are others who believe there is no association between diabetes and changes in the pancreas. HANSEMANN[6] analyzed the cases of diabetes which came to autopsy in the Berlin Pathological Institute during ten years, and the results follow:

[2] Medical News, 1897.

[3] New York Medical Journal, Dec. 4, 1897.

[4] Practice of Medicine, 1896.

[5] Quoted by Futcher, loc. cit.

1. Diabetes without changes in the pancreas, eight cases.
2. Diabetes without any information regarding the pancreas, six cases.
3. Diabetes with pancreatic disease, forty cases.
4. Pancreatic disease without diabetes, nineteen cases.

Of the forty cases in which the pancreas was affected, thirty-six presented atrophy, three fibrous induration of the organ, and one was a case of cyst of the pancreas.

WILLIAMSON[7] has examined the pancreas in twenty-three consecutive cases of diabetes, and in only twelve was the pancreas normal. He also analyzed 100 cases of pancreatic lesions in diabetes, which he collected from the literature and found that in forty-eight it concerned essentially atrophic changes; in seventeen it concerned fatty degeneration; in seven, cystic transformation; in fourteen, chronic fibrous changes; in two, hemorrhagic pancreatitis; in three, suppurative pancreatitis; in eight, carcinoma of the pancreas, and in one, calculi were present.

In connection with this it is of interest to note that LEPINE[8] maintains that the pancreas produces an active glycolytic ferment, which enters the blood and chyle and destroys a large part of the sugar before it reaches the liver, and that this ferment is absent, or greatly reduced in animals whose pancreas has been extirpated. More abundant evidence, however, seems to be required, according to FUTCHER, before this view can be fully accepted.

THE POLITICAL RESPONSIBILITY OF THE PHYSICIAN.

On various occasions heretofore the JOURNAL has endeavored to impress upon the members of the medical profession the utility and need of their taking a more active part in the government of this country, both as regards National and municipal affairs. The subject is one, however, that is not exhaustible by one or a few editorial utterances, and it is one that in some one of its many aspects is always demanding consideration. While the secular and religious papers are continually demanding the co-operation of good citizens in political affairs to prevent their being controlled, as is too often the case, by the bad citizens, it is certainly not out of place for medical journals to call the attention of its readers from time to time to their responsibilities in this matter. This is the more justifiable and necessary from the fact that heretofore we have as a profession neglected our opportunities and sinned away our mercies, to use an old Scotch expression, far more than we can reasonably excuse ourselves for, and have suffered in consequence. Professional self-respect has not been preserved by this abstention from public affairs to any extent at all comparable to the damage it has received by the education of the public through our neglect, to consider all so-called professors of the healing art, quacks and charlatans of every kind, as equally deserving of popular favor and legal countenance with the educated and conscientious physician. Recent legislation and legal decisions in various parts of our country are witness to this fact.

The duty of our profession to itself has been already editorially pointed out in this journal, and is only reiterated here to keep up the interest in the reform that is needed. It has also been pointed out that we owe a duty to our fellows and that of all men the physician is his brother's keeper, and his responsibility as a citizen and voter is correspondingly heightened. As individuals we feel this responsibility, but as a collective body we are apt to be remiss and forgetful in this regard, and evils that we could prevent are allowed full play. The interest of a physician in good government is something more than that of merely a good citizen; he is himself a guardian of the public in their nearest and dearest relations, and as such he has it as his duty to do all in his power to protect his charge from all evil legislation or vicious maladministration of salutary laws. In the matter of direct sanitation alone, the value of medical knowledge in the forming and execution of the laws and municipal regulations, ought to be sufficiently evident to require no demonstration. A writer in a recent issue of a religious journal calls attention to the fact that the gradual reduction of the rate of mortality in New York City from 25.18 to 20 in the last three years saved 3,758 lives in 1895, 7,736 in 1896 and 9,920 in 1897, a total of 21,414 lives, due to better government and closer attention to sanitation. If such a saving of human life can occur in one case it can in others, and if it is to be brought about elsewhere, or generally, it will have to be through the co-operation of enlightened medical opinion acting on official ignorance and stupidity. So-called practical politicians are too generally ignorant and indifferent in regard to these matters, and the community as a whole can act intelligently only under medical supervision and advice. A sanitary issue is almost, if not altogether, an unknown thing in our politics, and when it occurs it is handled, as a rule, along party lines and with all the disadvantages that such a course involves. Our legislatures are made up of lawyers and professional politicians without other visible means of support, together with a sprinkling of farmers and others who, though well meaning and generally honest, are apt to be prejudiced and misled on all matters that are without the limited range of their knowledge. If there are any physicians they are few in number and, as a rule, have not the influence that they should exert, even in matters that fall directly within their professional sphere, and in regard to which they should have a predominant voice. In Congress. as regards this special point of view, matters are no better; there has been, since RUSH's time, no really eminent medical man amongst our National legislators—we have no VIRCHOW or VERGA in our Senate or House of Represenatives. In the French Chamber of Deputies, there have generally been a number of physicians, and while the leading parts that some of them have taken may not have always reflected the most credit upon them, in medical questions they have often combined, and we do not hear of their inactivity when unintelligent legislation on medical and sanitary matters is proposed. The debates on medical matters in the British Parliament are of enough interest to be reported in British medical journals, and legislation in these matters is not left uninfluenced by professional action and information.

---

[6] Zeitschrift f. kl. Medizin, 1894.
[7] Med. Chronicle, May, 1897.
[8] Quoted by Futcher, loc. cit.

There is no reason why these conditions should not be attained in this country nor why, in our State legislatures especially, there should not be a working representation of the medical profession. who in all matters involving their special professional knowledge and the public health, should act together for the best interests of the community without regard to party lines Were this the case we might expect a beneficial reaction upon the profession itself; there would be less recognition of quackery and more appreciation of genuine scientific medicine on the part of politicians and the public, and with this a more satfactory status socially as well as politically. It would be a public benefit if we could have a few high-minded and able physicians to take part in National, State and municipal legislation in this country.

It is true that not every physician is fit to be a legislator and there are few probably that can afford it, and it is also true that some medical politicians have not been creditable representatives of their honorable profession. This, however, does not alter the facts we have stated, and further it does not at all affect the general question of the propriety of medical men recognizing their individual and collective responsibility as citizens, enlarged as it is by their special qualifications to judge and act in so many important matters affecting the public welfare.

MILITARY SURGEONS.

What's in a name?

This much: that the medical man of the military establishment has had his professional office limited in the popular mind to one, and that not the most important of his functions. As a "surgeon" he is supposed to lop off the limbs that the high intelligence directing the enemy's guns, and sometimes his own, has shattered, and, *ergo*, an amputating knife rather than a sword should be his distinctive badge of office; and *ergo*, again, a man whose badge is this has no fellowship in the military hierarchy.

The medical men of the military services have not acquiesced in this reasoning, but having been the under dogs in the fight, they have had to suffer and try to get strong, and the time has apparently come when they are strong enough to assert themselves and claim for their commissions the recognition and distinction merited by loyal service to the State from men of masterful acquirements in a profession requiring the highest order of ability—the very cornerstone of the military organization, without which the whole fabric would tumble to pieces.

The gun is useless without "the man behind the gun," and he is able and strong and intelligent as the military medical officer is empowered to select, domicile, feed, clothe and protect him from enemies within, as well as from those without, and when, rare event in his life. he may be disabled by hostile weapons, to repair and rehabilitate him.

The military surgeon is also military physician and especially military sanitarian. His forethought pervades the camp and ship, the regiment and fleet. Without him there can be no organized army and no disciplined navy. The military engineer may plan battles, the ordnance expert provide guns and ammunition, the steam engineer build mighty engines, and admirals and commodores, generals and colonels fulminate orders, but the blood and brawn and brains that are to fight the battles, operate the guns and animate the vessels are due to the professional prescience of the military medical officer, colleague and co-equal of the others.

The handsome volume of "Proceedings of the Seventh Annual Meeting of the Association of Military Surgeons of the United States," held at Columbus, Ohio, May 25–27, 1897, which has just been issued, demonstrates the *manifold functions of the military* medical officer. The papers contributed, without concert and on random topics, by officers of the Army, Navy and National Guard, from all parts of the country, have naturally fallen under certain heads, under which they have been appropriately grouped by the secretary-editor, Captain JAMES E. PILCHER of the United States Army, and these need only be enumerated to show the wi[illegible] c [illegible] medical c[illegible] province: naval [illegible] [illegible]gien[illegible] tary personal identification; clothing and accoutrements; military physical training; the proper type of the military medical officer; sanitary work among troops; transportation of the disabled; medical service in the field; the service of aid to the disabled; military surgery; military medicine; military medical problems, etc. The address of the President of the Association, Medical Director Gihon of the United States Navy, on "The Status of the Medical Officer in the Military and Naval Establishment," in terms lucid and unmistakable in intent, defines the place among military men to which these officers are entitled. By a happy coincidence the address in surgery at the sixty-fifth annual meeting of the British Medical Association, held at Montreal, Canada, September, 1897, by W. Mitchell Banks, M.D. Edin., on "The Surgeon of Old in War," in the words of the speaker, set forth "some of the most notable work done of old by a body of members of our profession, who have never received their due reward." After brief notices of Roman military and naval surgeons, of Ambroise Pare, Robert Clowes, Peter Lowe, John Woodall, Richard Wiseman, and Baron Larrey, of whom Napoleon wrote in his will made at St. Helena: "I bequeath to the Surgeon-in-Chief of the French Army, Larrey, 100,000 francs. He is the most virtuous man I have ever known." Dr. Banks referred to that enemy which assails fleets and armies, and against which only the medical officer is competent to lead and combat, "the pestilence more deadly than the sword," by which in the naval battles of the Seven Years' War as stated in the "Annual Register" for 1763, "it appeared there were but 1,512 sailors and marines killed, while 133,738 had died of disease or were missing." After narrating instances of conspicuous military courage on the battle-field in recent years by medical officers, who have been contemptuously designated "non-combatants," "brave civilians" and the like, Dr. Banks stated, "of the 118 wearers of the Victoria Cross, fourteen are surgeons, nearly 12 per cent. of the whole number and in the proportion of 9.5 per cent. of all the officers of the army." Despite all this, he concluded, "today Her Majesty's government can not induce candidates to come forward for the medical service of the Queen's army. And why? Because it has persistently treated the army medical department meanly and shabbily." Qualified medical graduates will not enter the British army, because the medical officer is not accorded the same status as to pay and precedence as officers of other corps. A similar reluctance to enter the medical department of our own Navy is indicated in the "Annual Report of the Acting Chief of the Bureau of Medicine and Surgery," just received, who states that there are "fifteen vacancies at the present time, nor does there appear to be any immediate prospect toward filling the corps."

It is not strange that civilians can not understand why, especially under a republican government, unfounded claims of inherent superiority of any one branch should operate to the extent of impairing the efficiency of the actual service. In fact, there is no tenable reason why there should be any lack of harmony in the composite organizations called the army and navy, in which each corps has well-defined equivalent duties, alike honorable and distinctive. The gist of Dr. Gihon's presidential address was a definition of the terms *grade, rank* and *title,* which indicates a seemingly practical basis of settlement of the vexed question of rank and precedence. "*Grade,*" he says, "is that something the law has conferred upon all commissioned officers, which serves to show each officer's place, position or status in a military organization." Grades are the steps, one above another, upon which the entire body of officers is grouped, irrespective of their special duties. *Rank* means simply seniority or precedence in the several grades, and depends solely upon the date of the officer's commission; thus one officer ranks another in his own grade. Grades are generic distinctions, and are practically the same all over the world. Rank is the relation of the individual officer to others of the same grade and naturally as well to those of other grades, so that in fact no two officers of the same service can have absolutely the same rank. Properly there is no name for rank, but custom has led to the identification of the name of the grade as rank. *Title,* the third of the terms used in the designation of officers, is the specific definition of their particular duties. Thus, surgeon-general in the army is the distinctive title by which an officer of the grade of brigadier general, who belongs to the medical department, is distinguished from brigadier generals of other departments. It is not desired nor would it be expedient, that specific corps titles should be abolished. Major Smith of the medical department does not wish to be confounded with Major Smith of the artillery, while he does wish it distinctly understood and admitted that he is as much a major in dignity, privilege and precedence as any other major. And herein lies the solution of the lamentable disputes which have estranged the staff, and it is, of course, the medical staff with which we have concern, and the line. Let the fact be distinctly understood that the military surgeon is not a mere make-believe soldier, an imitation officer, parading in borrowed plumes, seeking to hide his professional identity under distinctively military titles, nor that he is accorded by courtesy a quasi-status in military life to which in strict justice he has no legitimate claim. The honor and dignity of the profession of medicine require this and make it the duty of every physician in the United States to demand that the just recognition of the equivalent importance of military medicine, surgery and hygiene shall be made in the statutes, and this done, the Congress will be relieved of the importunities of those who charge on the one hand staff assumptions, and on the other line persecutions. When one or the other trenches upon statutory enactments, it is easy enough to punish the infraction. Physicians are law-abiding men, and it is certain that the military lawbreaker will find no more sympathy among his civil confrères than other offenders, but it will not do to assert that because a man is a "doctor," he and his field of work are not as honorable, as important, as responsible and as indispensable as those of other vocations inside or outside the military service. In our army, at least, if not in the British, the question is practically settled. In the rearrangement of the navy, it is hoped that the officers of the medical corps shall be placed on precisely the same footing as those of the army, in pay, privilege and precedence. If this be done, we predict there will be five applicants for every one of the fifteen vacancies which the chief of the medical bureau now laments.

PROFESSORS.

"I want a professor," cries the patient, and the ordinary every-day doctor who has no title must obey and call in consultation "Herr Professor." Of course, the patient does not know how professors are created; he does not know that any half dozen "scrubs" can start a medical school and dub themselves professors; he can have no knowledge of medical politics as they really are and therefore he insists on having a professor.

To the patient a professor means one who by years of study and experience has made himself so proficient in his special line that his fellow practitioners have deemed him worthy of appointment as a teacher and adviser. True, often a man has served a long apprenticeship as instructor, assistant, demonstrator, adjunct professor, etc., before he attains to the title of professor; but, too often, it is the man with the most "pull" who "gets there," the man who can obtain the best endowments for the college who is created professor over and above the faithful quiz-masters, privat-docents and clinical instructors.

About every large medical school is clustered a small army of assistants waiting for promotion, lobbying like ordinary politicians whenever a vacancy occurs, and as servile to those above them as a fourth-rate postmaster to his Senator.

What is there in the title of professor, that ma[illegible] so much to be desired?

It can not be altogether honor, since neith[illegible]dom nor great deeds are necessary to attain t[illegible] unworthy are as often made recipients of this [illegible] as the worthy. It is not the salary usually [illegible] with the office, since we know that many [illegible] go so far as to endow their own chairs. [illegible] others are at considerable outlay in keep[illegible] positions, and some have actually boug[illegible]fessorships. We fear that quite a num[illegible] about the colle[illegible] to compete for a professorship because indirectly there is money in it. A professor can command larger fees, because the layman thinks he has superior knowledge, and for the same reason those who can afford it prefer to visit the professors.

Certainly this can not apply to the teachers in such subjects as chemistry, pathology, anatomy and physiology, and most often there is some salary connected with these positions to compensate the incumbent. Indeed, in some schools the professors of so-called "practical" branches forego their own salaries for the sake of supporting these professorships. There was a time when medical colleges had only six or seven professors in their faculty; today the average is twenty-five. In one large Eastern city 7 per cent. of the medical profession have professorships in the colleges, and a great many more occupy positions as instructors and demonstrators.

But any one can become a professor of any subject providing he has the proper amount of influence. If no vacancy exists a new chair is created for his benefit. It does not matter whether he can teach or not; that is a minor consideration. All he needs to do is to compile a text-book, tell the students to buy it, and require daily recitations from this book. A book is very easily compiled; buy a few German and French books, translate them, or ask others to run over two or three late English and American books, get plenty of illustrations, change a word here and there and the book is complete. If the publisher own a medical journal, favorable reviews and plenty of advertising finishes the job, and the title of professor helps to sell the compound.

The publishers have not been slow to perceive this source of revenue, and by concentrating in one volume the products of many professors they produce a "text-book" which must be sold in many schools. No matter what the quality of the material, the profits [illegible] in this way, and the risk is nothing. for the [illegible] must buy this syndicate text-book nolens [illegible]

It is not always the men who compile books and [illegible] professorships who are the most learned or [illegible]ined physicians; and it is the great mistake of [illegible] medical profession that they put too much trust [illegible]ith in the words of men who possess such titles [illegible] they possess them. The character and stand[illegible] the school where he is professor should be [illegible] into account. The [illegible] medical man is too [illegible] to advise his patient to go to some professor, [illegible] of consulting with some honest, well balanced [illegible] practitioner. [illegible] studious and efficient [illegible] every city are [illegible] work, and yet are but [illegible] medical men who do [illegible] because they do not [illegible] known to the [illegible]. They do not hang [illegible] advertise. Adve[illegible] any case, they are not given to writing about wonderful cures obtained from strange remedies and reading reviews of other people's work before societies. They are not to be found in dispensaries, misunderstanding the poor patients who go there to receive relief, and because they do not do these things they are not invited to fill college chairs. But they are known to their patients, of whom they frequently possess more than many so-called professors. They are the men who keep alive the ethical spirit of medicine. They keep abreast of the times, even if they are silent. They are doing the heavy work, and the results they obtain, often amidst most unfavorable circumstances, are amazing. A time is coming when men who are prominent in the profession will not covet the title of professor, a time perhaps when the teaching of medicine will be a specialty in itself, and not merely a dodge to acquire practice.

When no medical schools shall be founded until there is need for it, and when all will put themselves on a scientific basis and look about them for teachers, for men who are qualified to instruct, the title of professor may have a real meaning, which at present it too often lacks. Let the general practitioner call the specialist to his aid because he is a specialist, and not because he is a professor.

CORRESPONDENCE.

Leprosy in Norway.

Vienna, Austria, Nov. 12, 1897.

To the Editor:—I was much surprised while visiting Norway during the last summer, to find that among a population of less than two million people, there existed three special hospitals for the confinement and treatment of lepers, and that in these institutions were domiciled over one thousand unfortunates, afflicted with this terrible disease.

By far the largest of these institutions is situated at Bergen, and while there I availed myself of the opportunity to visit it. The superintendent, Dr. Hansen, was away on a vacation, but his first assistant received me cordially, and answered all my queries in the politest manner possible.

Naturally, where a fish diet forms so large a part of the food of the population of this country, one asks the question whether this may not act as a strong causative factor in the production of the disease. I was told that this was not the opinion held by those most competent to judge; but that it was probably on account of the small, unhealthy and crowded habitations that the people occupy during the long cold winters in this rigorous climate, that the disease had gotten such a foothold.

Speaking to my host in a congratulatory tone of our almost entire exception from the disease in the United States, he answered me warmly and decidedly, saying: You have plenty of lepers in your country, but your physicians do not recognize the disease, and allow the patients to run at large, while here in Norway we diagnose the malady in its early stages and isolate the patients.

In a late visit of Dr. Hansen to the United States, he told me that the Doctor found three cases in the hospitals in Chicago, and twice as many in New York, as well as encountered several cases of true leprosy upon the streets of each city, all of whom were being treated for lupus, syphilis or some other form of skin disease. I asked why the disease did not spread if we allowed lepers to run at large. "Because," he replied, "where the hygienic conditions are favorable the disease is only very slightly contagious. None of the attendants in this hospital ever contracted the disease."

To fortify his position, the Doctor had me examine several cases where the disease only involved the skin, and asked me if these cases had consulted me at home, if I would have recognized the disease as leprosy; and I had to acknowledge that I would not have been able to have made a correct diagnosis if his was a correct one.

I have related this interview to a number of American physicians and all of them, except Dr. Moyer of Chicago, poohed at the idea what we could not correctly diagnose a case of leprosy. The latter related to me the case of a boy whom he used in his clinic to illustrate what he supposed to be one of syringomyelia, but which on further investigation he found to be one of true leprosy.

Medicine in Scandinavia.—Everywhere in Norway and in Sweden I find, both in medicine and surgery, everything to savor of a most distinctly German type. The physician speaks German, his medical books are largely German, and his surgical technique is often the fashion that one sees carried out in Berlin and Vienna.

Small children in Norway have a habit, it seems, of drinking a strong alkaline solution that their mothers use in washing clothes. This is likely to be followed by a stricture of the esophagus. I saw a case operated on in Christiania for the relief of this trouble, and there were two more cases under treatment for the same difficulty in the same hospital. If the case be a bad one a gastrotomy is first done, the walls of the stomach are united with the parietes of the abdominal walls, so that an external gastric fistula remains. A piece of rubber cord of suitable size has sewed to each end a thin piece of tape, so that when pulled upon, the rubber cord has a much smaller diameter than when not upon the stretch. A small bougie is fastened to one of these cords and is passed, via the esophagus, down through the stomach and out at the fistulous opening in the stomach. The rubber cord, now being put upon the stretch by means of the two pieces of tape, is drawn down into the esophagus in a condition where its caliber is greatly reduced. The traction upon the cords is now loosened and the rubber cord assumes its original size and thus expands the restricted esophageal tube. These rubber dilators are changed every three or four days, a larger one being used each time.

The patient is nourished for the first few days, per rectum, and after that through the gastric fistula. At Christiania I saw a number of cases of prostatic enlargement treated by a super-pubic cystotomy, and permanent drainage of the bladder through this incision.

The surgeon has devised an ingenious appliance for the after management of these cases, which allows the urine to pass off into a rubber bag, with little inconvenience to the patient and allowing him at the same time to be on his feet without being annoyed by being wet from the urine as it passes off.

At Odessa in Russia, I met Dr. Mariacholl, a bright man who devotes his entire attention to the diseases of the male genito-urinary organs. He is one of the surgeons of the general hospital in that city, and has an abundance of material at his disposal. He tells me he has castrated fourteen times and operated on the vas deferens thirteen times for enlarged prostate, with the result of benefiting none of his patients, and sending two victims to the insane asylum as a result of his interference.

He is bitterly opposed to the operation and says that the benefit surgeons claim to derive from it is only temporary in character, and is brought about solely by the patients being confined for a time in a horizontal position.

I was surprised to find on the table in the reading room of the general hospital at Odessa the latest medical journals in a half dozen different languages, and a set of men who seemed in all medical matters to be fully up to date.

To physicians who visit Sweden I can most warmly recommend that a few days be spent in the hospitals of the modern and thriving city of Stockholm, especially if you have some knowledge of German. Prof. Akermann, I believe, is one of the brightest men for his years I have ever heard teach or seen operate as a surgeon. Dr. Josephson does a large amount of abdominal work and is a great advocate of using buried silk sutures in closing up abdominal wounds, thus, he believes, avoiding the hernias that often follow these operations.

The surgeons here (I found the same thing in several other places) have abandoned catgut as a ligature, and are using fine silk in its stead, claiming that thereby they avoid suppuration and, if the silk used be fine, that it is absorbed without the manifestation of any local irritation.

Everywhere in Scotland, in Scandinavia, in Russia, in Turkey, in Greece and in Austria, I have found typhoid prevalent, and have been trying to do some missionary work as a Woodbridgeite, with what success I will tell the readers of the Journal in my next. W. S. Caldwell, M.D.

The Leprosy Question.

Translated from the French in *Janus* (July and August, 1897).

Copenhagen, June 26, 1897.

To the Editor (*of Janus*):—I see today with a certain displeasure that three of the publications, as numerous as they are little important, of Dr. Albert S. Ashmead, have been inserted in the sixth issue of your paper (May and June).

One of these publications, that entitled "Leprosy Overcome by Isolation in the Middle Ages," is absolutely useless. The author is pleased in this to attribute to me an opinion which I have never professed, *vide*, that the isolation of the lepers would be useless. *One will never find that opinion expressed in my works.* I am for isolation according to the Norwegian system, that is, the isolation of the diseased, who are incapable of taking care of and supporting themselves, and whose presence among other persons constitutes a real danger for the well. But I am not an admirer of the barbarians of the Middle Ages, who burned and imprisoned with horrible ceremonies the poor lepers, separating them from their families and their friends.

I know that Mr. Ashmead fights *for the wholesale isolation of the lepers* (even the 100,000 lepers in the English Indies), but I have the firm conviction that he will remain isolated himself with such a demand. The hygiene of our days does not act in the same manner as that of the Middle Ages.

Will you "kindly" ask Mr. Ashmead to quote in future the passages from my writings to which he refers, in order to avoid writing perfectly useless notes and attributing to me opinions which I do not have. I avail myself of this same occasion to interdict him, the copying without quotation of source, of photographs of my Icelandic lepers. These photographs were mine. I paid for them with two voyages, both perilous and disagreeable. Mr. Ashmead has inserted one of my photographs on the third page of his last pamphlet in the *Magazine of Medicine*, April, 1897, where he publishes, always without authorization of the correspondents, a number of letters, of which his own contains trifles, without interest, and also rude abuse of the leprologists of London, of Asmauer Hansen and myself. You will no doubt excuse me if I wish no longer to dispute with Mr. Ashmead, agree, Mr. Editor, the assurance of my perfect consideration. Dr. Ehlers.

New York, Dec. 6, 1897.

To the Editor of Janus, Amsterdam, Netherlands.—Dr. Ehlers says (*Janus*, July and August) I attribute to him opinions which he never professed.

Whether or not Dr. Ehlers stands for isolation was not the point at issue; it was, should isolation as a principle be promulgated by the Berlin Lepra-Conference? That was the important question. He stood an obstacle to our obtaining official delegates, claiming that governments *had always neglected the holy name of hygiene*, le saint nom de l'hygiène, in all countries and in all times. *It was not, in his opinion, the way that leads to the goal to try to stir up the governments. It is a congress which takes place between known leprologists and not a congress of leprology.* Our goal was not so much a congress of leprologists, which I have taken the liberty to call very frequently a congress for talk only. What we wanted with absolute singleness of purpose was a congress to take practical measures against a disease against which talk, disputations of leprologists, etc., had availed nothing, that is to do everything possible, in order to obtain universal measures of isolation. Therefore it was our object to stir up the governments. Although he does not speak against isolation in his works, his acts in opposing the call upon governments to take part in the Congress were against isolation. Some shadow of this government representation was nevertheless obtained, but it was due to *our* initiative, to the fight we made, not to Dr. Ehlers, and not even to *Asmauer Hansen*. Especially was it not due to the non contagion clique of London.

One word as to the photograph of which he interdicts the publication without quotation of source. Dr. Ehlers would seem to like such pleasant expressions as *interdict*, though he reproaches me with being *grossier:* but it is only fair to attribute the strength of his expressions to his imperfect knowledge of the delicacy of the French language. I published a photograph of an Icelandic leper woman, with his permission, giving him due credit in "Suppression and Prevention of Leprosy." I copied it as an instance of melancholia of leprosy, which is my own interpretation of it, in the *Magazine of Medicine* subsequently. His name did not appear in that second publication; it was simply forgotten. There is certainly in this no justification for such tremendous trumpeting about the world of the wrong done to his photograph, which he had paid for by two perilous and disagreeable voyages. I think it would be a useful exercise for Dr. Ehlers if he tried to insert the following truth into his brain: Dr. Ashmead had a perfect right to use subsequently without any ceremony a photograph which he had once published in the regular way, with permission and quotation.

Let me say to Dr. Ehlers that the mixed system of isolation of Norway has driven to the United States 17,000 Norwegian emigrants of *leprous families*, and thus served only to transfer the leper problem from Norway to America. *International* government laws, which I stand for, would prevent that.

If he considers this duly and seriously he will surely find that it is (though he says my publications are *inutiles*) more important, more useful to meditate upon than anything he has ever written in any of his works, published after such perilous and disagreeable voyages.

With a pleasant felicity, which is rare with Dr. Ehlers, he observes that it is I who shall *be isolated with my demand*, not so entirely isolated, however; for, as I said above, there was, in the presence of some government representatives, at Berlin something like a foreshadowing of international leper law.

We Americans are interested, I mean directly, not in our own leprosy, for we have none; we are interested in the leprosy of Norway, Japan, China, Hawaii and South America, to prevent the disease from being brought by emigration, which would easily be done by international arrangements, by stirring up the different governments. Even from the 159 lepers which Dr. Ehlers so successfully saw in Iceland, four have since escaped to this country, and almost while Dr. Ehlers gave himself up to the charms of the congressional, leprologist, non-international conference, these four contaminated Manitoba! Albert S. Ashmead, M.D.

License in Germany.

Toledo, Ohio, Dec. 10, 1897.

To the Editor:—Dr. Blech's ans[illegible] the inquiry as to the admission to the [illegible] edic[illegible] [illegible]rmany is not quite correct.

To be [illegible] [illegible]en [illegible] graduate from a gymnasium covering a classical course of nine years. These graduates are 20 years old on the average. After four semesters, usually during the fifth, the medical student passes the *tentamen physicum*, an examination in physiology, anatomy, physics, chemistry, physiologic chemistry, botany, mineralogy. Before passing the *tentamen physicum* the student is not admitted to the clinics. The candidate for *State examination* must have studied medicine and the allied branches for *at least* eight semesters, of which not more than three are allowed to be passed at a recognized foreign university. While eight semesters are the required time, it is by no means the average, which may be put at ten semesters.

A *foreign physician*, who wishes to practice in the German Empire, must furnish satisfactory proofs that his preliminary education is equal to the one required for matriculation from the German student of medicine. From the American physician the college degree of A.B. or A.M. is considered as equivalent. Upon the further proof that he is legally entitled to the practice of medicine in his native country, he will be admitted to the German State examination without attending one hour clinics or lectures or anything at the German school.

At this occasion I wish to correct the erroneous statement which is frequently heard, that the diplomas from a few American schools, like Ann Arbor, Harvard, Johns Hopkins, and some others, are recognized in Germany. It is not so! Their diplomas do not entitle to practice in Germany. Quite a number of foreign physicians are practicing in Germany, especially at watering places and similar sanitary institutions, and they had to fulfill the requirements as described.

Another class of foreign graduates in the German Empire is formed by professors at the universities, who not infrequently receive calls from one European State to another. These men only receive the State diploma without passing any examination. For instance: Billroth was a German graduate, but he received and accepted calls as professor to Zurich in Switzerland and to Vienna in Austria. Ziegler, the well known pathologist, is a Swiss graduate, and now in Germany. A number of Germans are professors in Switzerland, etc.

The requirements are about the same in all the different States in Europe. In whatever empire one wishes to practice medicine he has to procure the State diploma.

This explanation shows that Germany lays the most stress upon the preliminary education. The reasons are obvious.

B. BECKER, M.D.

Appendicitis.

EVANSVILLE, IND., Dec. 3, 1897.

To the Editor:—The alarming mortality rate following operative measures for the cure of appendicitis in this city has caused considerable comment of a questionable nature, recently and in the daily papers this morning the Board of Health has taken the matter into consideration. A recent case of operation during convalescence, and the patient's death in less than thirty-six hours, has opened the way to adverse criticism. In the case mentioned the operation seems to have been done through jealous rivalry, with a large fee as an incentive, which only too plainly demonstrates the fact that the surgeon above all others should be a man of unbiased mind.

During my twenty-six months of hospital work in Louisville, Chicago and this city, I have carefully observed the medical and surgical diagnosis and treatment of this disease and noted the difficulty in differentiating between it and typhlitis, perityphlitis, para-typhlitis, volvulus and intussusception and all forms of intestinal obstruction, and have arrived at the following conclusions;

1. An operation for appendicitis is usually demanded *the moment the diagnosis is absolute*, the condition of the patient and other indications justifying, provided the case is of the *progressive type* with the bowels locked, and treatment seems of no avail.

2. If the temperature is not high, the pulse is not irregular and not weak, if the pain is not intense; if the patient rests moderately well without, or with very little anodyne and the case seems to be of a *moderate type* and at a stand-still, then every effort should be made to move the bowel, reduce the inflammation and tympanites, soften down and carry out the inspissated feces, flush the bowel and *keep it open*, use intestinal antiseptics, tone up and sustain your patient and carry him through *without* surgical intervention.

3. If, after recovery, there still remains a sickening pain of a radiating character in the region of "McBurney's point," increased by the administration of strychnia or other agents stimulating peristalsis, denoting plastic adhesions and future trouble, a coated tongue and torpid constipated bowel, then tone up and build up your patient. Remove all offending material from the sigmoid colon and cecum by high enemas and hydragogue salines and remove the crippled disturber. Break up all adhesions under anti- and aseptic precautions, and your patient will stand every chance of a speedy and permanent recovery.

4. Do not as too many supposedly good surgeons have done, operate on a patient afflicted with appendicitis too soon after the crisis is over, and thereby stir up an inflammation afresh that is practically past.

Many a man's life has been lost by an operation performed at this time, when the patient was slowly but surely convalescing, with the bowel open, the pulse only slightly accelerated and temperature 99 or 99.5 degrees, and in fact when operative interference of any nature was *strictly contra-indicated.*

W. F. STERMAN, M.D.

"Edema Universalis."

NEW YORK, Dec. 10, 1897.

To the Editor:—Such little blunders, as forgetting that a word ending in "a" is not always a Latin feminine, but may be, and very often is, a Greek neuter, are exceedingly unpleasant and it takes a deal of philosophy to overcome the bitterness of being corrected. Yet, let me tell you of an instance whose mention must pour balsam into any such grammatic sore. When Victor Cousin published his Plato, he wrote the title thus or about thus: *Platonis Opera Omnia Victor Cousin Recollexit.* The book with that title was spread all over Europe, over all the world, in fact, causing everybody to ask how it could be that such a great man did not know the tenses of *recolligo.*

M.D.

The Word "Os."

SAN DIEGO, CAL., Dec. 11, 1897.

To the Editor:—Were I an editor I should not object perhaps to read the Old English *thon*, but I should draw the line as do you at the too common substitution of "orem" for the classic and correct accusative of that old neuter noun, *os.*

Truly yours. F.

PUBLIC HEALTH.

Control of Quarantine.

GOVERNOR BLOXHAM OF FLORIDA WRITES A LETTER ON THE SUBJECT.

GOVERNMENT SHOULD CO-OPERATE WITH THE STATES.

REASONS FOR A NATIONAL DEPARTMENT OF HEALTH GIVEN.

FLORIDA'S SYSTEM AN EXAMPLE OF EFFICIENCY.

TALLAHASSEE, FLA., Dec. 3, 1897.

Upon the request of the publishers of that journal, Governor Bloxham has written the following letter to the *New Orleans Picayune:*

T. G. RAPIER, ESQ., Manager *Picayune*, New Orleans, La.

Dear Sir:—I have the honor of acknowledging your favor of recent date requesting an expression of my views upon the question of State, interstate or Federal control of quarantine against the future invasion of disease. Never having worshiped at the shrine of Æsculapius, it will be impossible for me to present anything of a scientific character, but simply such thoughts as have been engrafted upon my mind by the experience of the last ten years in Florida and enforced by the views of the health authorities, in whose judgment I place great confidence. Were those thoughts summarized, they could be condensed in one expression:

Government co-operation with State control.

Our health authorities have frequently placed themselves on record in the matter of public health regulations. The State Board of Health of Florida is a unit upon the necessity of Federal legislation looking to the creation of a Department of Public Health with a recognized head. The members of the board at an annual meeting a year or two ago adopted a strong memorial to our State Legislature and our Congressional delegation, earnestly recommending concerted action in this direction. Could a cabinet officer be invested with a more responsible duty than looking after the health of seventy millions of people? Then why not create a Department of Health with a cabinet officer at its head, with ample power and authority to render assistance, when needed, but whose principle line of action and basis of union with the ideal public health system shall be co-operative and contributory to the several State boards of health?

NATIONAL DEPARTMENT OF HEALTH.

Let there be a "Secretary of Public Health," with State boards as his coadjutors. Let him formulate a uniform maritime quarantine and domestic or internal sanitary code to be enforced and operated by the several States.

The AMERICAN MEDICAL ASSOCIATION has embodied this idea, carried out in all its details, in a bill, which has received the indorsement of many of the leading sanitarians and public health organizations of the several States, and which I presume will be called to the attention of Congress with the indorsement of the great mass of the medical profession of the country. The country, and no portion so urgently as the Southern States, needs such a measure, or any course that will relieve a small bureau of the Treasury Department of the necessity of taking care of the lives of millions of people.

By what decree of Providence of common sense is it ordered that the financier of the Union—the Secretary of the Treasury—burdened with care beyond endurance, by environment and education harnessed to a most potential and engrossing charge—made the arbiter of matters of life and death to the countless thousands? Who more unfitted to deal with the great issues of public health than the steward of the nation's wealth? And why relegate to a mere departmental division a responsibility second to none, and one which should be confided to no care but that of the ablest and most experienced?

At present, Governmental health affairs are administered through and by the Marine-Hospital Service—an organization for the care of sick seamen, though nominally committed to the Secretary of the Treasury, who, perforce, both by reason or stress of other matters and the necessity of some medical culture, has to foist them upon a subordinate. And what record is attributed to this Marine-Hospital Service? It is claimed by those in a position to know that inadequate measures upon the part of this service not only admitted, but almost contributed to the infection at Key West and Tampa in 1887, which was followed by the epidemic of 1888. Who, then, was responsible for the epidemic of 1888?

Who was responsible for the entrance of yellow fever at Brunswick in 1893? Was there not mismanagement at that port? And who was in charge of its maritime quarantine?

Who is responsible for the introduction of the recent plague in the first instance, through Ship Island Quarantine Station, near Biloxi? Was anything accomplished by this service to prevent a further spread of the disease after its careless introduction? Was confidence established, without which the country may always expect the barbarities of the shotgun quarantine?

The answer to these inquiries, which are not aimed at individuals, but at the system, must necessarily have weight in determining future legislation. Let us have a Department of Public Health, most assuredly, but let it be advisory and co-operative, and upon lines that will be an earnest of satisfactory and successful administration. Florida has been virtually free from yellow fever for eight years, and what few cases have appeared have been promptly stamped out.

What more striking lesson than that presented by Florida's health record during the months of September, October and November of this year, when intercourse between the cities and towns of the neighboring States was hampered, when not totally inhibited, by local quarantines? While within this State no embargo of any description rested upon freight or passenger intercourse, and you came and went at will without even the suggestion of quarantine.

The reason is not obscure. Florida, after its experience of 1888, like the people of the whole country at this time, had its attention directed to a future invasion of the disease, and called into existence a system which its years and successes have demonstrated to be thoroughly efficient, and which has so won the confidence of the people that it has been enabled throughout the exigencies of the past summer to at once allay apprehension and suppress excitement.

To the student of the matter, Florida's part in the yellow fever history of this year evidences not only the capacity of our health officials, but the wisdom of our system, and arouses a desire for a similar condition in other States.

Should a co-operative and contributory system, as suggested, ripen into proper legislation, those in charge should be well qualified to take into consideration your inquiry as to the best means of preventing a recurrence of the epidemic, and at the same time minimizing the embargoes of commerce.

Very truly yours, W. D. BLOXHAM.

The Bubonic Plague still furnishes items to the press. Its ravages, according to a Bombay dispatch dated December 6, are still unabated at Poonah.

The War Against Typhoid Fever Germs is brisk in many centers of the milk supply in New York and New Jersey. The sources are found in the dilution with polluted water and the careless cleansing of cans. The Health Boards are to be hardly blamed for a want of vigilance, certainly not in this summary waste of the materia morbis.

Health in Chicago.—The report for October shows that the total number of deaths were 1,716 or 1.05 per 1,000; the rate for the same period in 1896 being 1.06 per 1,000. Of these 1,716 deaths, 419 were persons under 1 year old, 180 between 1 and 5 years old; 191 were due to acute intestinal diseases, 208 to nervous diseases, 193 to consumption, 134 to pneumonia, 96 to diseases of the heart, 61 to typhoid fever, 61 to diphtheria and membranous croup, 60 to bronchitis and 58 to cancer.

Health in Michigan.—Reports for November show consumption, remittent fever, typhoid fever, intermittent fever, pneumonia and erysipelas less prevalent as compared with the average for November during the 11 years, 1886-96. Consumption was reported in 172 places, typhoid fever in 111, diphtheria 66, scarlet fever 57, measles 37, whooping cough 18, and smallpox one place, this being a decrease from the October reports as to consumption and typhoid fever and an increase as to diphtheria, scarlet fever, measles, whooping cough and smallpox.

NECROLOGY.

JOHN BERRIEN LINDSLEY, M.D., Nashville, Tenn., died December 11. Dr. Lindsley was graduated from the University of Nashville in 1839, afterward taking his Master's degree there in 1841, in which year he began the study of medicine. He received the degree of M.D. from the University of Pennsylvania, Department of Medicine, in 1843. He devoted the years 1845 to 1850 to the study of natural science and in 1859 took courses of instruction in European institutions. In 1850 he began teaching medicine at Nashville, Tenn., where he has passed his life as a practical educator. From October, 1850 to April, 1873, he was Professor of Chemistry and Pharmacy in the Medical Department, University of Nashville, and was Dean of the Faculty until 1855, having been one of the founders of that institution in 1850. Largely through his influence was brought about the creation of a normal school, which has been in successful operation since 1875. From 1877 to 1879 he was Secretary and Executive Officer of the State Board of Health of Tennessee, and again since 1884, President of the Board from April 1 to July 1, 1884, and Professor of Chemistry in the Medical Department, University of Tennessee from 1889.

The Doctor was a prominent member of many societies, among them the Tennessee State Medical Society, American Medical Association, American Academy of Medicine, American Association for the Advancement of Science, American Public Health Association, etc. He served at Nashville during the cholera epidemics of 1849, 1854, 1866 and 1873, and in 1878 was in charge of the yellow fever refugees to that city. Dr. Lindsley edited the reports of the Nashville Board of Health for 1877-79, reports of the Nashville Board of Health 1880 to 1884, and the *State Board of Health Bulletin* 1889 and 1890 to 1894. Other works from his pen are numerous. In the reports of the American Historical Association, 1889 to 1892, twenty-nine titles of papers from his pen are mentioned. In addition to his medical and sanitary work, Dr. Lindsley devoted considerable time to ecclesiastic labors, being ordained in 1846 by the Presbytery of Nashville and for several years thereafter acting as minister to country churches and slaves connected therewith. The College of New Jersey (Princeton University) conferred the degree of S.T.D. on the Doctor in 1858, and since 1891 he has been Lecturer of Sociology in the Theological Department of the Cumberland University, Lebanon, Tenn. The Doctor was born at Princeton, N. J., Oct. 24, 1822, being a direct descendent from one of the earliest English settlers of the New Haven Colony.

Charles Harvey Quinlan, M.D., D.D.S., Evanston, Ill., December 6, aged 76 years. Dr. Quinlan had been a resident of Chicago and its suburbs since 1846. He came from Albany, N. Y., where he was born Feb. 19, 1821. Immediately after his graduation from a dental school at Buffalo he opened an office in Chicago. He at once became one of the most prominent men of his profession in the city. The introduction here of sulphuric ether as an anesthetic brought him fame. It was in the fall of 1846, when the method of application was discovered in Boston and full instructions for its manufacture and use were sent to Dr. Quinlan by his uncle, Dr. Harvey of Buffalo. Ether was then known as a letheon, and Chicago is the first city west of the Alleghanies where it was given a practical test. This test was given in a public clinic at Rush Medical College, where an amputation was to be performed. Dr. Quinlan was asked to be present and administer the anesthetic. Wide publicity was given the test, and the result was entirely satisfactory. The newspapers of the country teemed with accounts of the experiment and Dr. Quinlan was given great praise. Shortly after this, chloroform was discovered, and the formula was immediately procured by Dr. Quinlan. He was the first to distill this anesthetic in Chicago. Dr. Quinlan took the degree of M.D. from Rush Medical College in 1865, and practiced in Lake Forest until his removal to Evanston in 1875. Since then he has lived a quiet life at his residence, 1619 Chicago Avenue. He built the Avenue House, Evanston's fashionable hotel in 1882. He was one of the founders of the Lake Forest University, being one of four men to give $1,000 each to start that school.

Alexander W. Stein, M.D., New York University, 1864, died at his home in New York from cirrhosis of the liver, December 5. He was born in Buda-Pest, Hungary, fifty-seven years ago, and when 4 years old was brought to this country by his father, Louis Stein, surgeon-general of the revolutionary army and a friend of Kossuth. As a lecturer on surgery, professor of physiology in the New York College of Dentistry and a writer he was well known to the profession. He was delegate or attendant at most of the medical congresses here or in Europe.

J. Harvey Manning, M.D., Chicago, December 6, aged 38 years. He was educated at Cornell College, Iowa, and graduated from the College of Physicians and Surgeons in 1890. He afterward took a two years' course in Columbia College of Physicians and Surgeons, New York, graduating in 1892. He spent a year in St. Elizabeth's hospital, and later a year in the Iowa State Insane Asylum. He began regular practice in Chicago in 1895.

Mark H. Lackersteen, M.D., Chicago, December 7, aged 62 years. The Doctor was a professor in the Post Graduate Medical College. In his early years he took an active part in the famous Sepoy mutiny in India, besides holding high positions under the British government.

Joseph F. Edwards, M.D., Atlantic City, N. J., December 6. Dr. Edwards was born in Philadelphia, Dec. 8, 1853, and was a graduate from Georgetown College and the University of Pennsylvania and practiced medicine in his native city for sixteen years. He was formerly a surgeon of the Second Regiment, N. G. P. Dr. Edwards was the founder and former editor of the *Annals of Hygiene* and the author of *Edwards' Journal of Health*. He was a member of the Board of Managers of the Trenton Insane Asylum, also of the New Jersey Board of Health. He was formerly of the Pennsylvania Board of Health.

G. Perry Reynolds, M.D., New York University Medical College, 1852, medical examiner for Guilford, Conn., died December 9, aged 68 years.——Robert N. Short, M.D., Miami Medical College, Ohio, 1871, died suddenly of cardiac disease at his home in Mechanicsburg, Pa., December 1, aged 66 years.——Mark Van Winkle, M.D., College of Physicians and Surgeons, New York, 1855, died in Little Falls, N. J., aged 73 years.——James F. Murray, M.D., Albany, 1866, of Gloversville, N. Y., died from abscess of the liver December 5, aged 52 years.——Dr. Jacquemet, *agrégé*, professor in the medical faculty of Montpelier, aged 72 years.——Dr. Poisson, Professor of Surgical Pathology in the Medical School of Poitiers.——Dr. J. B. Bottero of Turin, editor of the *Gazzetta del Popolo*, and the oldest journalist in Italy, aged 81 years.——Dr. A. Jazenko, some time privat docent of surgery in the University of Kieff, aged 55 years.——Dr. Cristino Cebrian, Professor of Anatomy in the University of Salamanca.——Dr. Arthur Scheffer, some time Professor of Chemistry and Physics in the University of Moscow, aged 65 years.——Dr. A. Gadaud of Périgueux, Senator for La Dordogne, and for some time Minister of Agriculture, aged 56 years.—— Dr. Paul Guterbock, privat docent of surgery in the University of Berlin, and Dr. Zinn of Eberswalde, for many years one of the leading medical psychologists of Germany, aged 72 years.——W. M. Anderson, M.D., Charles City, Iowa, December 2, aged 63 years.——J. Spofford Hunt, M.D., Chicago, December 10, aged 63 years. During the war the Doctor served as surgeon of the Third Illinois Cavalry.— R. H. Johnston, M.D., Cromwell, Iowa, aged 61 years.——R. A. Kirkpatrick, M.D., Montreal, aged 34 years.——George A. Munro, M.D., Providence, R. I., a veteran of the Civil War, December 3, aged 60 years.——George Q. Orris, M.D., Seymour, Ind., December 3, aged 47 years.——John M. Small, M.D., Lewiston, Maine, December 4, aged 80 years.——R. T. Worley, M.D., Baton Rouge, La., of yellow fever, November 29.——James H. Pooley, M.D., Toledo, Ohio, December 10, Dean of the Toledo Medical College, suddenly.

BOOK NOTICES.

The Peritoneum. By Byron Robinson, B.S., M.D. Chicago. Part 1. Histology and Physiology with 247 illustrations. Chicago. 1897. 8vo. Cl. C. V. Waite & Co., 70 State Street.

Books of this character have not been very common in this country, but we are developing a class of students that by earnest plodding and scientific work will eventually bring our work up to a level with the best literature abroad. There are many expressions that we do not admire in this book, there are some specimens of the misuse of words and some mistakes of proof reading, but when the whole work is fairly examined it will be seen to be comprehensive, thorough, honest and creditable. We fear that Dr. Robinson will hardly receive the great credit he deserves for his hard labor, but let the reader of this handsome volume stop for a moment to reflect what great industry was required in its compilation alone, to say nothing of the vast number of original experiments undertaken. It is, we believe, safe to say that a very large percentage of practitioners have a quite imperfect knowledge of the peritoneum, and especially its histology and physiology. The work under consideration will greatly aid in acquiring the knowledge so generally lacking in the text books, and will be welcomed as filling a distinct gap in modern medical literature. The illustrations are well executed, the paper is good, and the type is large.

Pictorial Atlas of Skin Diseases and Syphilitic Affections, in Photo-lithochromes from the models in the museum of the Saint Louis Hospital, Paris. Ernest Beurier, A. Fournier, Tennyson, Hallopeau, Du Castel, physicians to Saint Louis Hospital, Paris, with the co operation of the Honorable Henri Feulard, Curator of the Museum and L. Jacquet, former House Physician. Edited by J. J. PRINGLE, M.B., F.R.C.P., Physician to the Department for Diseases of the Skin at the Middlesex Hospital, London. Part 12. London: Rebman Publishing Company. Philadelphia: W. B. Saunders; W. T. Keener, 52 Randolph Street, Chicago agent.

This part, which completes the set, contains five plates with seven illustrations, pictorial representations of the unrivaled models of Barreta, the original of which are in the museum of the St. Louis Hospital. The explanatory text accompanying these magnificent plates is the work of professional masters and therefore needs no special comment.

Plate 46 contains the hypertrophic form of syphilitic chancre of the nostrils. The diphtheroid form of syphilitic chancre of the tonsils by Alfred Fournier.

Plate 16 in the accompanying text, Xeroderma Pigmentosum, by R. Du Castel.

Plate 48, Impetigo Contagiosa, by Lucien Jacquet.

Plate 49, Urticaria Pigmentosa with Atrophic Spots, by H. Hallopeau.

Plate 50, Syphilitic Chancre of the Lip: 1. Scabbed form; 2, erosive form, syphilitic chancre of the tongue (ulcerative form) by Alfred Fournier.

The practitioner is fortunate who can secure for his library these beautiful reproductions of the collection of models in the famous Paris hospital.

Index Catalogue of the Library of the Surgeon General's Office, United States Army, Officers and subjects. Second series, Vol. 2. B-Bywater, Washington: Government Printing, 1897, pp. 954.

This volume, according to Dr. Huntington's statement, includes 15,732 author-titles, representing 6,383 volumes, 14,802 pamphlets; it also contains 5,774 special titles and special books and 21,725 titles of articles in periodicals.

This magnificent index, which has reflected more credit on American medical literature than almost any other work, and has done more to make the medical literature of the work available than any other, is progressing at the rate of two volumes a year, and in the same careful and accurate manner characteristic of the preceeding volumes.

We extend our congratulations to General Sternberg and Deputy Surgeon-General Huntington on the successful continuation of the work, and thanks to the wise Congress which by timely and liberal appropriations made possible this great undertaking.

Archives of the Roentgen Ray. We have received the July number of the "Archives of the Roentgen Ray," formerly Archives of Skiagraphy, London. Edited by W. S. HEDLEY, M.D., and SIDNEY ROWLAND, M.A., and the Editorial Committee. London: Rebman Publishing Company. Chicago agent, W. T. Keener, 52 Randolph Street.

The *Archives* has been modified in form and greatly increased in size from the former publication, and its scope is very materially broadened. By careful following of the pictures and studies of Roentgen one will be able to prevent the mistakes into which he otherwise would be liable to fall. The progressive surgeon can scarcely afford to be without the *Archives*.

Vade Mecum of Ophthalmological Therapeutics. By Dr. LANDOLT and Dr. GYGAX. Pages 138. Philadelphia: J. B. Lippincott Company. 1898.

This handbook is arranged in alphabetic order so that an index is not required, and is intended to give the essentials of ophthalmic medicine to the practitioner and students preparing for examinations.

It is a handbook for immediate reference. Translation has been well made by Dr. E. H. Neyman of Milwaukee with the consent of the author. Formula given in both decimal and English terms.

Lectures on Physiology. First Series. On Animal Electricity. By AUGUST D. WALLER, M.D., F.R.S. Pp. 144. London, New York and Bombay. 1897.

This work contains part of the material of course of twelve lectures on animal electricity delivered by the author at the Royal Institute during the spring of 1897.

There are six lectures giving the results of various experiments on animal tissue. These lectures are fully illustrated and are intended for advanced workers in the field of animal electricity. It also shows very fully how the modern lectureships depend more upon the laboratory than upon the lecture theater.

About Children. Six Lectures given to the Nurses in the Cleveland General Hospital in February, 1896. By SAMUEL W. KELLY, M.D. Cleveland Medical Gazette Publishing Company. 1897.

These lectures constitute a pretty successful attempt to bring technical information within the reach of nurses. Pupils at nurses' training schools generally will find the book full of information and therefore very useful to them, not only in acquiring necessary knowledge, but after graduation as a book of reference.

A Handbook of Midwifery. By W. R. DAKIN, M.D. Four hundred Illustrations, pp. 629. London, New York and Bombay: Longman, Green & Co. 1897.

This work is intended for students and junior practitioners. The subject is arranged in two divisions, those of physiology and pathology. The author has intended to make the work of high practical value without introducing any unnecessary details.

The printing is good, the illustrations are excellent and the work is very full and complete. By using fine type the publishers have succeeded in introducing as much matter as is usually found in the larger text-books.

Lippincott Company's Pocket Medical Dictionary; Including pronunciation and definition of twenty thousand of the principal terms used in Medicine and the allied sciences, together with many elaborate tables. Edited by RYLAND W. GREEN, M.D., Editor of Lippincott's Medical Dictionary. J. B. Lippincott Company, Philadelphia and London: 1897.

This is a pocket medical lexicon, handy in size, convenient, accurate and full, and contains more words than are to be found in most pocket lexicons, although it has omitted antique and obsolete terms. It will be found very useful.

MISCELLANY.

Medicine and Pharmacy in France.—The law which at present governs the practice of medicine in France, forbids the simultaneous practice of medicine and pharmacy, even by a person who may be in possession of diplomas in both subjects.

Bathing in London.—Foreign ideas of the British sense of propriety will receive a shock from the recent order of the London county council that men and boys bathing in public ponds must wear drawers. Hitherto they have bathed naked, and the minority in the council opposed the innovation as an "undemocratic step."

Pulmonary Phenomena of Hysteric Origin.—E. Leoni describes, in *Il Morgagni*, No. 6, a puzzling case of apparent pulmonary tuberculosis, with fever, râles and other symptoms of pulmonary trouble. They changed their position from one day to the other; sometimes on the right, the next day on the left, or absent altogether. Moral persuasion, suggestion and electricity resulted in rapid and complete recovery.—*Gazz. d. O. e d. C.*, August 15.

Clonic Movements in Syringomyelia Exclusively of Medullary Origin.—Marinesco has been studying, with various registering apparatus, the clinic movements in this disease, affecting mostly the fingers. They sometimes assume the character of a partial epileptic attack of cortical origin, and have been attributed to the motor zone of the brain. He finds, on the contrary, that they are convulsive attacks resulting solely from the medullary irritation, independent of any cortical intervention.—*Bulletin de l'Acad. de Méd.*, August 17.

Pathology of the Lachrymal Canaliculi.—Mitvalsky describes the cystoid protuberances that develop in these canaliculi, and states that besides those in which the actinomyces are found, he has observed a case in which the contents were the empty shells of starch grains, the starch having been removed by chemic action.—*Wien. Klin. Rund.*, October 31.

The Theory of the Toxic Effect of Extensive Burns is confirmed by the results of Tommasoli's recent experiments with dogs, to which he administered the serum or meat extracts of other dogs that had been burnt. The invariably fatal effect was averted however, if, at the same time, he injected artificial serum, which he considers the logical treatment for extensive burns. He reports one very severe case saved by injections of artificial serum and another which showed marked improvement after each injection, although the patient finally succumbed to his injuries.—*Cbl. f. Chir.* from *Monatsheft f. Prakt. Derm.*, Vol. xxv, No. 2.

Delay in Mailing.—For the first time since the fire, our mail was delayed last week. We had purchased at considerable expense a cutting machine known as Sheridan's "Auto." For the last three weeks the "*Auto*" failed to work when wanted by reason of breakage, breaking down when just in the midst of the edition. The Sheridan Company having received their money have taken little interest in its working, and left the office to fix up its machinery as best it could. We are sincerely sorry to have the delay inconvenience our members, but it has been unavoidable.

Construction of Medical Practice Act.—While some attack was made on the New Mexico statute "to regulate the practice of medicine," etc., approved Feb. 27, 1895, the supreme court of New Mexico assumes it to embrace a rightful subject of egislation. It also holds, in re Roe Chung, Aug. 25, 1897, at there is nothing unconstitutional in the provision of the atute that the penalty denounced is to be recovered in an action of debt, which is converted into a fine proceeding to enforce its collection. And it holds that a justice of the peace has jurisdiction of an action to recover the penalty for a first offense, which is $100. In this, it holds that a statute of 1889, providing that for all fines and costs imprisonment may be suffered at the rate of $1 per day until the days amount to the fine and costs, should be read into the act of 1895.

Can Refuse to Sell Coffins.—Not only may a heartless grocer refuse to sell a starving man provisions, but an undertaker can refuse to sell a coffin for the burial of a dead person and can refuse to accept employment in his capacity of an undertaker. Such is the decision of the court of appeals of Kentucky in the case of Brewster against Miller. More particularly does the court decide here that an undertaker is not bound to accept employment or furnish articles necessary for burial where the person asking for same is indebted to him for previous services. The court says that one has the right to decline to enter into a business undertaking with anyone. It also holds that to afford mutual protection against such persons, it is not unlawful for the undertakers of a community to associate themselves together and agree to refuse to render a like service to one who has refused or failed to pay such expenses in the past to some member of the association.

The Solubility of Gallstones in Oil.—To determine the solvent power of various oils on gallstones, Scott (*British Medical Journal*, No. 1917, p. 7[illegible]) exposed in a warm chamber at 98.4 degrees, beakers containing from 20 to 50 c.c. of oil, the quantity varying according to the size of the stone used in the experiment. After immersion the stones were removed from time to time, gently dried with filter paper and weighed. The oils employed were pure olive oil, pure almond oil and the odorless and tasteless purified petroleum oil known as parolein. The stones used in the first experiment were passed by a patient in whom treatment had been employed with olive oil with some success. They were about the size of dried green peas, facetted, friable, and dark greenish brown in color. As they dissolved, they showed a thin outer brownish layer of pigment, a thick middle layer light yellow in color consisting largely of cholesterin, and a small dark nucleus of pigment. They dissolved with about equal readiness in the different oils, losing approximately one-quarter of their weight in twelve hours, one-half in twenty-four hours, and three-quarters in forty-eight hours. After thirty-six hours' immersion, little was left but the nucleus. The stones used in the second experiment were removed from the gall bladder by operation. They were considerably greater in bulk than those of the first experiment, being somewhat larger than cherry stones. They were hard in consistence and appeared to dissolve uniformly, maintaining their original brownish yellow color. In the process of solution they exhibited no well defined layers. They seemed to contain a larger amount of pigment and salts than the other stones and lost a much smaller percentage of their weight during corresponding periods of immersion in the oil. After four days those immersed in olive oil had lost rather more than half their original weight, those immersed in almond oil exactly half, and those immersed in parolein less than one-third. The stones used in the third experiment were obtained from the same source as those used in the second. They were of enormous size, being as large as filberts. Although they commenced to dissolve in one hour, the loss of weight per cent., as time went on, was not nearly so great as in the previous experiment. At the end of the twenty-five days, those immersed in olive oil had lost rather more than half their original weight and those immersed in parolein rather more than one-quarter.

Earth Worms as Propagators of Disease.—Dr. Halsted Boylan of Paris has recently presented some ideas concerning the cause of yellow fever, charbon and tetanus, and he claims that the worms coming to the surface of the earth from the bodies of those buried who have died of these diseases frequently act as propagators of the germ or poison. The earth itself becomes contaminated and the poison is inhaled by man, eaten by cattle or infects the water, which afterward becomes a fruitful source of disease propagation. Verneuil has called attention to the fact that tetanus is most frequent among those coming in any way into contact with horses, it only being necessary for men under these conditions to have upon their hands a small cut, scratch or wound inadvertently brought into contact either with the manure containing the bacillus or with the ground infected thereby. The first experiment of this kind was made by Nicolaier, who demonstrated that the subcutaneous inoculation of earth taken in the fields, gardens and streets determined in mice, rabbits and guinea pigs, at times septicemia by septic vibrios and at others tetanus. The contamination from below the surface is two fold; miasma and emanations from the soil in paludial districts or when particles of organic substances rise to the surface in different states of alteration, coming from the tissues of decomposing animal matter and by the ordinary rain worm. W. Theobald in a recent lecture claimed that in 1850 yellow fever appeared in the Valley of the Amazon where it had been previously unknown, and a careful investigation traced its origin in that locality to the burial of a man from Jamaica who had died from the fever and had been landed at Para for burial. The soil on the surface was found to be charged with the microbes of yellow fever. The question now rises whether typhoid and malarial fevers may not be also disseminated in this manner. The one has its bacillus of Eberth and the other its hematozoon of Laveran. Both are very resistant and the worms may swallow particles of them and deposit them on the surface with the same facility as the bacilli of yellow fever, although this method of transmission of typhoid and malarial fevers is not generally admitted. Pasteur has found the germs of charbon in the superficial layers of the earth over ditches where sheep that had died of the disease several years previous had been buried. The earth worms are the first carriers. In the depths of the soil they swallow minute particles of earth containing the spores formed around the cadavers of men and animals, for the purpose of extracting from them what nutritive substances they may contain and rendering them on the surface in the form of little twisted cylinders of a dark brown color. The practice of cremation is strongly urged to destroy these dangerous elements of both the bodies of those having died of the contagious and infectious diseases and the soil surrounding their place of burial.

Telegraphy Without Wires by the Marconi and Rubens Methods.—The *Consular Reports*, September, has a communication from Consul General DeKay, at Berlin, regarding the present status of the above subject-matter, interesting to the profession. The latest work in this direction appears to have been done by Rubens of Frankfort who is an instructor in electric physics at the Berlin Policlinic. Marconi experimented from the British mainland to an island four marine miles distant. He used a generator of electric waves invented by the late Professor Herz, which generator throws the waves of electricity in all directions, as the rays of light emanate on all sides from a flame. The problem was to concentrate these waves of electricity in one direction, namely, toward the island. This he did by placing a concave mirror behind the Herz generator, by which the waves were reflected and made parallel in the required direction. On the island he placed what is called a "coherer," that is to say, a tube filled with particles of metal of just the right size and quality for the purposes now to be set forth. The coherer was set before another concave mirror, so placed that it would catch the electric waves coming parallel across the water from the concave mirror and Herz generator on the mainland. The coherer was set exactly at the focus. Imagine that the Herz generator on the mainland is a flame whose light rays are caught by a concave mirror, thrown over to the island, caught there in another concave mirror and focused on the coherer. Now, the metal particles in this coherer are so adjusted as to size that the whole may be likened to a violin string which vibrates when a certain sound is made by the voice. As one can tune a violin string to a certain note, so one can find the metal particles that will vibrate to an electric wave of a certain size. Try to pass an electric current through these particles at ordinary times and there will be no result; but when the waves generated by the Herz generator, coming from a distance, fall on these particles, a vibration is set up in them, they touch each other, and a charge of electricity applied to the tube is allowed to pass through and can be registered in the usual way. Thus, the coherer, being supplied with an ordinary battery and Morse electromagnet, permits the circuit to be closed when the electric waves from the mainland reach it. The click is registered only when the rays or waves from the Herz generator are reflected on it. The electric waves are not believed to be vibrations in the air itself, but rather in the ether between the particles of air. As compared to light waves, they are of enormous relative size. It will be noted that the electric current on the island sent through the coherer has no other office than to strengthen and register the effects of these waves or rays caught by the concave mirror and focused on the coherer. Professor Rubens, a young German of Dutch extraction, recently delivered an address at the Polytechnicum in Charlotten-Berlin, before a number of instructors, in the course of which he said:

"Since Herz's death in 1888, much progress has been made in reducing the size of the electric-wave generator. As the size of the apparatus has a relation to the length of the electric waves, and as it was desirable to shorten these waves, the decreased size of the apparatus has been of use in making air telegraphy more practicable. Shorter electric waves are more approximate in their action to waves of light, and go further. Up to the present, the shortest are those of the Russian experimenter Lebedew, who has produced them from 6 to 7 millimeters long. Professor Rubens showed a thermo-element or heat catcher, invented by himself to take the place of Marconi's coherer, which catches, like the coherer, the refracted and focused electric rays. The spark, he observed, was not at all a necessary phenomenon in electricity. He then made many curious experiments to show the similarity in action of waves of light and waves of electricity, and also drew attention to the very different way in which electric and light waves pass through different substances. Thus he reflected electric waves like light, refracted them with prisms, and diffracted them with a wire grating of parallel wires, as light is diffracted by Langley's grating. He then showed the polarization of these rays—freely, through the fibers of wood longitudinally; and badly, across the fiber; easily, through closed books with the leaves; and with difficulty, across. Thus a pile of books or sheets of glass showed polarization like crystals under light. He showed, also, that on account of the length of these waves, their energy was absorbed differently by different substances: thus, 1, water absorbs all the energy; 2, metals absorb all the energy; 3, glass absorbs nearly all; 4, paraffin absorbs hardly any, and 5, hard rubber absorbs hardly any. Thus they move through hard, black rubber and paraffin as light moves through air, glass or water, that is to say, with hardly any resistance, while glass lets very little of them through, and metal and water are impervious to them. Professor Rubens imbeds his Herz generator in petroleum for better isolation, and, as a handy concentrator of the electric waves or lens, uses a round glass bottle filled with petroleum. By placing in turn the glass prism, wire grating, block of wood, pile of books, water, paraffin and hard rubber in the line of the unseen electric waves pouring from the generator and concentrator toward the wave catcher, he showed on an indicator the passage, easy or retarded, of the unseen flow or its entire interruption."

Detroit.

The Regular Meeting of the Wayne County Medical Society was held December 2. Dr. W. T. Corlett of Cleveland, Ohio, read a paper on "Recent Researches in Ringworm." The paper was illustrated with lantern slides and microscopic specimens, showing the different clinical varieties of the disease and the microscopic features. The doctor, who is a disciple of Sabouraud of Paris, gave as the divisions of ringworm, tinea tonsurans, tinea sycosis and tinea circinata. He divided the fungi which cause ringworm into the trichophyton microsporon, trichophyton megalosporon endothrix and ectothrix, each of which produces a distinct clinical variety of ringworm. The first produces ringworm of the scalp in children of from 2 to 15 years of age. It is extremely rebellious to treatment except on hairless surfaces. The second produces nearly all cases of tinea circinata of the body, eczema marginatum and sycosis without folliculitis. It is much less contagious than the first variety and yields very readily to treatment. The third fungus is supposed to be of animal origin. In childhood it gives rise to kerion and in men to sycosis accompanied with deep suppurative folliculitis. The clinical features of each variety of the disease were minutely described, together with the microscopic features of the hairs involved. For the treatment, thorough cleanliness, epilation of the hairs, chrysophanic acid, oleate of mercury and of copper and boracic acid were recommended, and the specific treatment for each variety was thoroughly discussed.

A Meeting of the physicians of Detroit was called by the local board of health on Saturday afternoon, December 4, to discuss the necessity of placing tuberculosis and whooping cough in the same category with diphtheria, smallpox and such diseases, placarding the houses where tuberculosis and where whooping cough exist and isolating the patients infected with such diseases as proposed by the State Board of Health. There were about forty of the representative physicians of the city present. After discussion, the following resolution was unanimously passed: "That it is the sentiment of this meeting that it is unnecessary and inadvisable to placard, isolate, or in any way make public the fact that any person has consumption, but that it would be advisable to educate the public through the physician by suitable literature from the Board of Health. Further, in assisting the physicians, it would be advisable for the health board of the city to institute bacteriologic examination of sputum." Whooping cough was then taken up, and it required only three minutes to discuss and pass a motion discountenancing the proposal to include it in the list of contagious diseases.

HEALTH REPORT for week ending December 4: Births, male 39, female 36. Deaths 69, of which 25 were children under 5 years of age. Contagious diseases: Diphtheria, 13; scarlet fever, 61; deaths from diphtheria 4, none from scarlet fever.

Dr. C. B. EGGEMAN of this city died on November 30. He was the son of the late Dr. Rudolph Eggeman, and was born in Detroit, March 23, 1857. He was a graduate of the Detroit College of Medicine, class of 1879. After taking his degree he went to Philadelphia and attended the Ophthalmic College, and then began the practice of his specialty of diseases of eye and ear in Detroit in 1881. He was a member of the Masonic fraternity and of several other local societies.

THE 44TH SANITARY CONVENTION OF MICHIGAN was held in Detroit under the auspices of the State Board of Health, December 9 and 10. President Thomas W. Palmer addressed the convention. Papers were read by Prof. Frederick G. Novy, M.D., of Ann Arbor, "Germs, What they are and how they Produce Disease;" by Hon. Frank Wells, President State Board of Health, Lansing, "Statement of the Objects of the Convention;" by Guy L. Kiefer, M.D., Detroit, "Isolation and Disinfection of Persons and Things;" by Miss Harriett Marsh, Principal of Hancock School, "Popular Education in Sanitary Science;" discussion of the subject by Prof. S. Emory Whitney, principal of Cass School, Detroit, and Prof. Delos Fall, member of State Board of Health, Albion; by Charles T. McClintock, M.D., Detroit, "From the Purely Scientific Standpoint;" by Chas. G. Jennings, M.D., Detroit, "From the Physician's Standpoint;" by Oscar Le Seure, M.D., member of Detroit Board of Health, "From the Standpoint of the Local Board of Health;" by John McVicar, president of the Board of Public Works, "Streets and Alleys and Their Relation to the Public Health," discussed by Mrs. L. H. Trowbridge, Dr. J. E. Clark and Dr. Longyear.

Washington.

HEALTH OF THE DISTRICT.—The report of the health officer for the week ended December 4 shows the total number of deaths to have been 83, of which number 44 were white and 39 colored. The principal causes of death were: consumption 11, heart disease 5, pneumonia 14, typhoid fever 2.

MEDICAL SOCIETY.—At the recent meeting of the Medical Society Dr. Deale read an essay entitled the "Climatic Treatment of Pulmonary Tuberculosis," and presented specimens of fibrosarcoma of the uterus. Dr. Stone presented specimens of extrauterine pregnancy and appendicitis. Dr. Allen read a paper on "Senile Epilepsy." Dr. Caldwell presented a specimen of cancer of the stomach, and Dr. Acker presented a specimen of tubercular tumor of the brain involving the cerebellum and pons.

WASHINGTON OBSTETRICAL AND GYNECOLOGICAL SOCIETY.—The 271st meeting of the Society was held on December 3. Dr. Acker read a report on two cases of acute purulent peritonitis in infancy.

Hospitals.

ST. LUKE'S HOSPITAL, Borough of Manhattan, New York City, at the annual meeting in December showed that the death rate from all causes for the year was 10.3 per cent. In the medical department 1,201 cases were treated, and 1,243 in the surgical department. In the patient or dispensary department, which was opened on Nov. 4, 1896, 2,608 new patients have been treated and 9,930 visits made. The total house expenses for the year were $153,299.04. A report made by the building committee stated the cost of the new buildings to be $1,749,605, which, added to $530,000, the cost of the land, brings the total outlay up to $2,279,605. The deficiency of income as against expenses for the year ending Sept. 30, 1897, was $57,499.25.

Societies.

The following meetings are noted:

Connecticut.—New Haven Medical Association, December 2.

Georgia.—Athens Medical Society, December 2.

Illinois.—McLean County Medical Society, Bloomington, December 2.

Indiana.—The Perry County Medico-Surgical Society, Tell City, was organized December 4.

Iowa.—Iowa Central Medical Society, Marshalltown, December 14; Polk County Medical Society, Des Moines, December 7.

Maine.—Portland Medical Club, December 2.

Massachusetts.—Eastern Hampden Medical Association, Springfield, December 2.

Minnesota.—Hennepin County Medical Society, Minneapolis, December 6; Minnesota Academy of Medicine, Minneapolis, December 1; Minnesota Valley Medical Association Mankato, December 6.

New York.—Glens Falls Medical and Surgical Society, December 2.

Ohio.—Cuyahoga County Medical Society, Cleveland, December 1; Logan County Medical Society, Bellefontaine, December 5.

Pennsylvania.—Harrisburg Academy of Medicine, December 3; Lebanon County Medical Society, Lebanon, December 1; Luzerne County Medical Society, Wilkesbarre, December 6; York County Medical Society, York City, December 2.

CHANGE OF ADDRESS.

Appleby, T. E. W., from 226 Summit Ave to 48 E. 4th St., St. Paul, Minn.

Bullard, W. M., from Wickes, Mont. to Fall Brook, Cal.

Fisk, [illegible] F., from Chicago, Ill. to Waterloo, Ind.; Friedel, A. H., from 27 Waverly Pl. to 828 W. Monroe St., Chicago, Ill.

Hanna C. U., From Palaskala to 46 So. 6th St. Zanesville, Ohio.

Langdon, F. W., from 65 W. 7th to 5 Garfield Pl. Cincinnati, Ohio; Litvin, A., 538 So. Halsted to 568 W. 14th St., Chicago, Ill.; Lagorio, A., from 65 Randolph St. to 228 Dearborn Ave, Chicago, Ill.

Moody, H. A., from Bailey Springs to 988 Government St., Mobile, Ala.; Miner, A. L., from Ponsford, Minn. to Bellows Falls, Vt.

Pomeroy, H. M., from 200 W. 118th St. to 222 W. 23d St., New York, N. Y.

Rugg, D. F., from Hartland, Vt. to Adirondack Cottage Sanitarium, Saranac Lake, N. Y.

Straley, S. B., from Andover, N. J. to Pasadena, Cal.; Shastid, T. H., from Galesburg, Ill. to 202 N. Washington St., Battle Creek, Mich.

Thomas, J. D., from the "Cairo" to 1181 Connecticut Ave, Washington, D. C.

LETTERS RECEIVED.

THE PUBLIC SERVICES.

Army Changes. Official List of Changes in the Stations and duties of officers serving in the Medical Department, U. S. Army, from December 4 to 10, 1897.

Capt. Madison M. Brewer, Asst. Surgeon, is granted leave of absence for four months from the date of his departure from Ft. Keogh, Mont.

Capt. William O. Owen, Asst. Surgeon (Ft. Bayard, N. M.), is granted leave of absence for one month.

Navy Changes. Changes in the Medical Corps of the U. S. Navy for the week ending December 4, 1897.

P. A. Surgeon S. S. White, detached from the "Concord" and ordered to the "Wheeling."

The Journal of the
American Medical Association

VOL. XXIX. CHICAGO, ILL., DECEMBER 25, 1897. No. 26.

ORIGINAL ARTICLES.

EXTRA-UTERINE PREGNANCY, WITH REPORT OF CASES.

Presented to the Section on Obstetrics and Diseases of Women, at the Forty-eighth Annual Meeting of the American Medical Association, at Philadelphia, Pa., June 1-4, 1897.

BY M. PRICE, M.D.
PHILADELPHIA, PA.

In considering the condition of extra-uterine pregnancy there are very many questions of great professional interest, some not yet finally settled, all relating to the condition; giving light upon its treatment is of vast importance to the practitioner. It is important that he should be familiar with all the more prominent symptoms of an accidental misplacement or deviation from lines of normal pregnancy.

All cases of suspected pregnancy in women who have had a longer or shorter period of sterility, should be carefully watched in the early months for symptoms of tubal gestation. I do not know of a single case of rupture, or the history of rupture with well marked symptoms of loss of blood, that the rupture did not take place before the twelfth week.

All these cases must of necessity first pass through the hands of the general practitioner, and are lost or saved through their appreciation of the symptoms and their ability to make a diagnosis.

If the real character of the accident goes unrecognized, the great majority of these cases of extra-uterine pregnancy perish; death is almost certain and in very many instances sudden.

They perish in the majority of instances because of the failure of the physician to make a diagnosis; they perish of hemorrhage, septic peritonitis, obstruction of the bowel, etc.

That there are instances of recovery in ectopic pregnancy, without surgical interference, we are not prepared or disposed to dispute, for there being instances of recovery we have the testimony of men who by their wide experience are entitled to speak with some weight of authority. Numbered among these are the eminent English surgeons, Tait, Greg Smith, Taylor and others. Recoveries are reported by a number of American surgeons.

Our earlier gynecologic literature, that antedating our advances in abdominal surgery, abounds in the reports of cases where symptoms and conditions, the entire clinical history, could only be interpreted in our present light as ectopic pregnancy.

These cases augmented the statistics of every practitioner's mortality. They were classed under the head of hematocele. There has been very considerable useless groping around by surgeons in settling the nomenclature of this trouble. We are gradually settling into a common sense simplicity of terms. The symptoms, the actual perils of the condition bother us more than those confusing, misleading or obscure names under which too many things medical and surgical pass or, to speak more accurately, stay. With names as with operations, the more simple and intelligible the better. Because exceptional cases recover, we can not afford the risks involved in delay, the long suffering, if not death, to which the patient is exposed. We can not determine in any given case the probability of recovery. We know this condition kills, that the only certain relief is good clean surgery and that in the hands of men with a prolonged surgical experience few die.

The word "variety" used in connection with ectopic gestation has very little practical interest to those of us whose sole object is to save life. Speaking for myself, from my own experience and observation, whatever may have been that of others, I have never seen in my own work, nor in that of Dr. Joseph Price (numbering together more than 175 cases), but one variety, that of tubal pregnancy. And I have seen them in all stages from the first to the tenth month, and have yet to see the first case developed in the broad ligament. I have seen the ovary stretched over and part of the capsule enveloping the child, which by some would probably have been called an ovarian pregnancy.

The symptoms of extra-uterine pregnancy are almost infallible. It is rare indeed for the symptoms of this condition to be taken as evidence of some other trouble, but it is not an infrequent occurrence for other conditions to be taken as extra-uterine pregnancy.

Lawrence Tait has made this subject one of such thorough investigation, and has taught us the lessons of his wide and successful experience, that it would seem that little aside from what he has said is worth saying. We can not do better than to follow his teaching and record as successful experiences. We can offer very little excuse for making mistakes in diagnosing this condition. There can be but two, ignorance or carelessness. It may occur repeatedly; it does occur that the practitioner recognizes the condition, but is without that surgical experience which would enable him to surgically deal with the condition. In this situation the duty is plain, that of promptly calling in the assistance of one as expert in the surgery of such cases as is at command. The duty is equally imperative upon the surgeon to promptly respond. Where the issue is one of life, no mere personal prejudices or questions of loss or gain should restrain or influence professional action.

As to those cases which go to term I will give my own opinion, deductions of my own experience. The possibility of these cases going to term is not disputed. Conclusions from my own observations may not accord with those of others of the profession. I have seen three cases at or near term. In each case the child was encapsuled in an amniotic sac and not in the broad ligament. My reasoning is that the fetus is forced through the rent in the tube encapsuled in its amniotic sac. And if the placenta has sufficient attachment to continue the life of fetus until the placenta has made new attachments, the child continues to develop in its sac surrounded by the abdominal viscera, coming in contact with it, forming adhesions and in this way materially aiding and strengthening the walls of the sac. I am of opinion that the reason why we so often find the fetus absent in undoubted cases of tubal pregnancy is not only that the tube has been ruptured, but also the amniotic sac, and the fetus is forced into the general peritoneal cavity where a few days will suffice for its digestion.

As to just how soon the fetus can possibly be protected by the amniotic sac I am unable to say. I have found the fetus not longer than a Lima bean, but it was in those cases where the primary rupture and the operation for the relief followed immediately. It is rare indeed to find a child where there has been several attacks or several severe hemorrhages, but you find everything else, the ruptured tube, placenta and all that pertains to a ruptured tubal pregnancy save the fetus. I have seen a number of cases, from the second month on, where it could be clearly demonstrated that the child was within the amniotic sac. In this connection Tait uses the following language: "I have at the present moment lying in these very rooms a fetus of the full term which I removed from among the intestines, and round which nearly complete amniotic membranes were to be seen." I do not deem it possible that a child could live long at any period of gestation free in the peritoneal cavity. My conviction is that it would be encapsuled by the omentum or protected by an inflammatory barrier in some way. There are a number of cases on record, but there is very little to explain or show how long y had been so placed or how protected. Very ny of the recorded cases give a very unsatisfactory nical history and few of those interesting phases racteristic of these cases.

My case at term, reported some five years ago ere both mother and child lived, was in the tenth nth of gestation and in the amniotic sac. When nurse attempted to wash the child she found that the slightest rub of the wash rag she would take skin off. The child would bleed from every point touched, showing that the child was already being ested alive. The mother and child are today both ng and well, the child a beautiful little girl. I will pardoned here for a moment's digression. This e is reported in Gregg Smith's system of abdom- l surgery as operated on by one Dr. Eastman, no of the name known to belong to the profession of iladelphia. This goes to illustrate the worthless racter of the statistics of even eminent authority. is case is stated by Smith to be the only one in rica where mother and child both lived. As he manner of dealing with the placenta, where it ssible the placenta should be removed. Where s not contracted adhesions outside of the pelvis, involving bowel and mesentery in its attachments, re is probably less danger in its immediate removal n to treat it in any other way. It is only rarely t you can obtain a pedicle and control hemorrhage ligature. The gauze pack is probably the only thod in many cases by which hemorrhage can be ntrolled. *Up to the beginning of the fourth month* there is no trouble in controlling hemorrahge by ligature. From the fourth month on, hemorrhage is the most serious complication. The second method of dealing with the placenta is what is called the open method of treatment, the one used in my case of term with the result of saving both mother and child. In this case, for thirty-five consecutive days, this woman with an abdominal wound six inches in length, with the amniotic sac stitched to the wound, endured daily the packing of the wound with from four to five yards of bichlorid gauze, this over the face of the placenta, covering a space as large as the rim of a man's hat. It was attached to everything from the left cornu of the uterus, descending colon and part of the transverse colon and over the entire face of the left kidney. The placenta was black and gangrenous in appearance and owing to the desperate condition of the patient, three determined efforts were made to remove the placenta. These efforts had to be abandoned on account of the frightful hemorrhage. Gauze packing in each instance stopped the hemorrhage at once.

On the tenth day, when the first attempt at removal was made, her temperature dropped to 96 degrees. The temperature chart indicated variations of temperature from 96 to 105 degrees; this for thirty-five days. At this time the whole left side of the body seemed to contract just as the uterus does in labor, with free discharge of blood. I at once removed almost the entire placenta, cutting it loose with the fingers just as we do from the uterus in a partially detached placenta, meeting with about the same amount of difficulty. There was free hemorrhage which was controlled by gauze pack. This immense opening had almost entirely closed in a week's time. I am positive that after my experience with hemorrhage, sepsis and other accidents incident to this manner of treating the placenta, I would not again resort to the practice of the open method and leave the placenta to slough away. It is out of the question to talk of removing the placenta in these cases at time of the operation, for the patient would beyond doubt perish from hemorrhage. I believe it to be better to cut short the cord, thoroughly clean the face of the placenta, remove all loose membranes and clot and close the abdomen, trusting to absorption, or later, when the condition of the patient indicates the necessity for a second operation. This impresses me as the safer procedure because it can not possibly offer any poorer chance for the patient than the open treatment. When the placenta is placed in the pelvis and is attached to either ovary, tube, uterus or pelvic wall, and it may only be slightly to abdominal viscera, the entire uterine mass can and should be removed at the time of operation at any cost, but when the placenta has formed attachments to vital organs and over a large surface, the patient would perish if removal of the placenta was attempted. These questions can only be decided by those who have many times dealt with such cases; it is nonsense to say that any surgeon can deal with the complications always possibly involved in this condition. He must be an abdominal surgeon trained by many experiences, with a knowledge of all the varying conditions met with in these cases and the surgical confidence to grapple with any possible emergency. The reference of these cases to those trained by special study, long clinical experience and observation brings no opprobrium upon the general practitioner, whose care is of the general public, the treatment of the more general ailments. His time and study are too much taken up for him to become expert in major operative procedures. The common diseases of women and children, and obstetrics, one of the most important branches of medical practice, open a wide field for usefulness and honor. The wounded patient, whether by disease or accident, is entitled to the best skill.

In the report of nine cases in the London hospitals, in the later months of extra-uterine pregnancy, five perished, certainly a large mortality. These cases were probably in the hands of some of the best general surgeons in the world, but we should infer from the mortality that they were men not specially trained in abdominal surgery. In extra-uterine pregnancy there is no time for the discussion of symptoms, easy chair deliberations, for consulting the books or literature of the subject. collecting an armament of instruments—there is always urgency and there should always be readiness. Ninety-nine times in a hundred the operation is to save life from hemorrhage. Usually sufficient time has already elapsed to leave the patient pulseless and in collapse. This collapsed condition results from two causes: 1, from direct loss of blood; 2, from intraperitoneal pressure on the abdominal sympathetic nervous system. The urgent indications are the immediate stoppage of the hemorrhage. The only way to do this is to open the abdomen and tie the vessel; *no matter what condition of collapse the patient is in, so she is not actually dead.*

More than half the cases I have operated on have been pulseless at the wrist, and to all intents and purposes almost at their end. In many of these cases, as soon as the abdomen was opened and the ligature applied, the hemorrhage stopped, and after the great quantities of free blood in the peritoneal cavity, in many cases amounting to two or three quarts, was removed, there would be a moderately good pulse at the wrist. A statement made by Dr. Hobart A. Hare of Philadelphia may have some bearing in this connection. In a discussion, he called my attention to experiments he had made by forcible injections of water into the peritoneal cavity of a dog. and that it would kill him much quicker and with a very much smaller quantity of water than if injected into the bowel. I believe this goes to explain the quick recovery from the grave symptoms of ruptured extra-uterine pregnancy after operation. The hemorrhage is stopped and the pressure removed from the sympathetic nervous system. If the practitioner has not or can not diagnose a case in hand correctly, it is criminal for him to permit his patient to go an suffering while he refuses or neglects to call in advice. It is to be presumed that when a man operates for extra-uterine pregnancy, that he has made a diagnosis. There can be but little shock in an operation that involves only two inches of the abdominal wall, the delivery of the specimen and the application of the ligature. How is it possible for any one to justify delay when we compare this procedure with the actual condition of the patient, hemorrhage and intraperitoneal pressure, with everything pointing to speedy dissolution. Later, in the surgical treatment of this condition, say from the fourth month to term, before operation, there are questions to be considered more important than that of hemorrhage. We have then to consider the dangers during and after operation and how to deal with them. It is these very dangers and how to deal with them that have interested the profession. The later months with the attendant risks are anxious months for the patient and attending physician if real conditions are realized. The profession is not of one opinion as to the plan of surgical procedure and after-treatment in cases of extra-uterine pregnancy when they have passed the fourth month.

I am of the opinion that no matter at what period of gestation a woman may be in, an effort should be at once made to end the pregnancy by surgical means, for there is not an hour that the patient is not in danger, and every day that the fetus is allowed to remain the risk to the patient is increased, and for that reason there should be prompt, unhesitating interference to terminate it.

The united surgery of the world has only been able to save from eight to ten children where these cases have reached term, with a mortality to the mother and an anount of suffering that by no possible argument, with the simple claims of humanity in the balance, could justify.

If the peritoneum can be left with everything removed, with a well-placed glass drainage at the lower point of the wound, the result will be perfect. If the hemorrhage can not be controlled without a gauze pack we should then depend on gauze drainage, which, while it will save life, greatly prolongs the after-treatment. The toilet of the general peritoneal cavity should be perfect. It should be faultlessly clean and kept so. If there has been contamination from any source there should be thorough cleansing with clean boiled water.

Case 1.—Mrs. Y., operated on Jan. 20, 1896, for extra-uterine pregnancy, supposed to be in the tenth week of pregnancy. About two quarts of liquid and clotted blood were removed at the time of operation. The child was partially digested. The patient made a good recovery.

Case 2.—Mrs. L., patient of Dr. Burroughs, Trenton, N. J. Operation April 19, 1896. Tube ruptured near its end. The placenta and about a quart and one half of blood obtained. Glass drainage for three days. Patient made a good recovery.

Case 3.—Mrs. S. S., patient of Dr. Edwards of Williamstown, N. J. There was not a very large quantity of blood, probably about a quart. Rupture had taken place several weeks before I saw her. Liquid portions of the blood had been absorbed. Fetus was not found. Placenta and tube were removed. Irrigation and glass drainage. Tube removed on the third day. Satisfactory recovery.

Case 4.—Mrs. T., patient of Dr. Hubler, Pittston, Pa., Dec. 5, 1896. Operation. A moderate quantity of blood, irrigation and drainage. Placenta, tube and ovary all removed. Recovery.

Case 5.—Mrs. W., patient of Dr. Shea. Extra uterine pregnancy; about the twelfth week. The contents of sac suppurating. Patient septic. The sac, placenta and tube were removed. Irrigation. Glass drainage for four days. Recovery.

Case 6.—Mrs. L. G., patient of Dr. Nock, Philadelphia. Mrs. G. is a thick-set woman, twice married, and during her first marriage had a number of provoked miscarriages, some of which must have left the tube in condition favoring extra-uterine pregnancy. After her second marriage both she and her husband desired children, so were much pleased when the wife developed symptoms of pregnancy. They had been married three years when, as they supposed, this much to be desired accident happened. She missed her period on Jan. 11, 1897, followed by sick stomach and severe pain in the abdomen on or about February 15. She suffered with very severe pain in the abdomen followed by a weak faint feeling which sent her to bed. This condition was followed by a slight bloody discharge which continued to increase until March 16. During this time she had a number of these attacks of pain followed by a weak faint feeling, with constant tenesmus and desire to go to stool, but could not accomplish anything. On March 16 I was called to see the patient by the following note from her attendant, Dr. Nock: "I have in my opinion a case of tubal pregnancy with rupture. Can you come at once and operate?" I operated at once and found the conditions as stated by her attendant correct. The woman made a beautiful recovery. In this case no fetus was found; the rupture probably had forced the child into the peritoneal cavity and it was there digested. The placenta was living and adherent to the end of the tube.

Case 7.—*Extra-uterine pregnancy.*—Mrs. M. C., age 31 years; one child 5 years old, a boy; always a strong, healthy, robust woman; had one miscarriage; last menstrual period on

Nov. 28, 1896; December period missed. On Jan. 28, 1897, while washing her feet, she felt some little pain in the abdomen. After going to her room the pain increased, accompanied by symptoms of fulness in the bowels with severe tenesmus. She went to the water-closet feeling that the bowels must be relieved at once. Nothing passed from the bowel.' The fulness and tenesmus increased. She made ineffectual efforts to relieve the bowel; this is the last she remembers. Her husband found her in a dead faint on the floor, very pale and pulseless. A physician was called who said she was suffering from peritonitis. The severe pain and distension of the abdomen he said all indicated peritonitis. From this time on until March 14, when I first saw her, she had a number of paroxysmal attacks of great pain accompanied with great weakness. There was a slight bloody discharge almost continuous after the first rupture in January. She had all the classic symptoms of extra-uterine pregnancy: Sterile for a number of years; a missed period; sick at the stomach; pains in the breast; intense pain with collapse and symptoms of hemorrhage, in the constant slight discharge of blood as in miscarriage, and at the end of the twelfth week a shedding of an entire cast of the uterus. At the end of the fourth month I was asked to take charge of her. Her condition was desperate. A weak thready pulse, a peculiar nervous condition so often found in these cases, bordering on insanity. She could not sleep and could not be persuaded but that death was impending. The physical examination revealed a tumor extending to the umbilicus, hard and tender and almost as a fibroid. The uterus was pushed back and fixed in the pelvis. The cervix was soft, open and bleeding as in miscarriage. The entire pelvis was filled up with the pregnancy and blood clot. She was at once sent to Dr. Joseph Price's hospital and, as soon as she could be prepared, with Dr. Price's assistance I removed the entire mass, capsule, baby, placenta and all.

I do not know whether the baby was alive when delivered. I rather think not from the appearance of the child, and it was the opinion of those present that it was dead. I do not know that the placenta was very much alive. Some bowel stitching had to be done and hemorrhage controlled by the gauze pack. The placenta was in front of the uterus and over the left tube and filled up the left side of the pelvis. No ligatures were used. The appearance of the gestation sac was that of muscular tissue adherent to everything it came in contact with; it had no connection with the broad ligament except at those points where it came in contact with it, as it did with other pelvic contents. I have seen three pregnancies at term and many others at different stages of pregnancy, and I have the first one to see that was located in the broad ligament, but I have seen a number that had the appearance of being so located.

The capsule had much the appearance of the thickened broad ligament. In many cases of operation for the removal of extra-uterine pregnancy, it has to be removed from under the broad ligament and not from within its folds. I have now had half a hundred of these cases in all stages of their development and have never found one in the folds of the broad ligament. This has been the experience of my brother in now nearly 150 of these cases, with many of which I assisted him; nor have either of us ever seen a case of hematocele in all our work.

This patient has made a most satisfactory recovery. As she recovered from her accident and the operation, her mental condition constantly improved so that at the end of ten days her mental condition was restored. I have seen the symptom of anxiety and fear amount to terror of approaching death so that some one had to be at the bedside to constantly assure them that all was going well with them. I had one case that this condition lasted for ten days, with every other symptom the most favorable. This patient cleared up as if a veil had been removed, and was as bright and happy as she was before miserable and unmanageable.

The child in the case just reported was in its own amniotic sac. I have seen three extra-uterine pregnancies at term, or so nearly that no one could say they were not. The children were all delivered alive, but two of them only lived for a short time and the other is living and now over 4 years old. They were all in the amniotic sac and the head of one was well up under the ribs. I do not believe that an extra-uterine baby can live any great length of time in the free peritoneal cavity. Those that do and go on developing have been forced through the rent in the tube and encapsuled in the amniotic sac with sufficient attachments. If the rupture in the tube ceases to bleed, the pregnancy goes on to term or operation or the death of the child or the mother, or both, more frequently both.

THE VAGINAL ROUTE IN OPERATION FOR RUPTURED TUBAL PREGNANCY.

Presented to the Section on Obstetrics and Diseases of Women at the Forty-eighth Annual Meeting of the American Medical Association at Philadelphia, Pa., June 1-4, 1897.

BY J. WESLEY BOVÉE, M.D.

GYNECOLOGIST TO COLUMBIA AND PROVIDENCE HOSPITALS, AND CLINICAL PROFESSOR OF GYNECOLOGY IN COLUMBIAN UNIVERSITY.
WASHINGTON, D. C.

Ruptured tubal pregnancy has been so forciby kept to the front during the past fifteen years, that many of the profession have been led to think it is a condition in which, without exception, the life of the individual suffering from it is in great danger. We are obliged to believe it is not so dangerous in many cases, and that quite often it escapes attention either from the little discomfort caused by it, or from the physician failing to realize the condition and procrastination allowing the absorption of the escaped blood. This latter variety can not include a very large percentage of cases however, or it would more often be found as a complication of other forms of pelvic disease. We have reason to think also, that occasionally Fallopian tubes are ruptured by over-distension from blood, not due to pregnancy, but mistaken for that condition. We have recently had such a case in our own practice.

It is not the purpose of this paper to deal extensively with the general subject of ruptured tubal pregnancy, but to mention particularly the variety best operated on through the vagina. It is that special variety in which the hemorrhage has not been the most severe, has been stopped by the outer pressure of the lost blood and in which the omentum, either alone or with other structures, has formed a barrier to its progress upward into the abdominal cavity, that we think can be best operated for through the vagina.

It manifestly would not be available to select the vaginal route to control hemorrhage from an ovarian artery, or to remove from the abdominal cavity a large amount of free blood. *But for those cases in which* hemorrhage has stopped and the free blood has remained in the pelvis and is retained there by a petition from nature, no other route is as safe, quick and efficient as the incision through the roof of the vagina behind the cervix. While this is not the only variety of ectopic pregnancy in which this route is satisfactory, we wish to limit our remarks to this one kind.

The clever work of Howard Kelly, Miller of Utica, Reynolds and others in this operation, is well known and leaves very little to be said concerning the technique of the operation. The paper that Kelly read before the American Gynecological Society last year, mentions thirteen cases operated on in this manner with but one death, and that one not due to the operation *per se*. He has given in his paper the precise details and steps of the operation as well as the dangers of it, and we can only endorse his description. We have not found it necessary to continue the gauze packing as long as he recommends, and our patients have been allowed to sit out of bed about two weeks after operation, and to walk about a week later.

The difficulty concerning this method of operation is in differentiating the cases to which the vaginal route is applicable from others that demand abdominal section. We must be quite certain the loose blood is in the pelvis only. Of this we can never be absolutely certain, and for that reason we should be prepared for abdominal section in all cases of diagnosed ruptured tubal pregnancy that are to be attacked through the vagina. Lest valuable time be lost by attempting the vaginal operation first, in cases requiring laparotomy, considerable care is necessary in the physical examination of the cases. A careful examination through the abdominal walls is not sufficient. Vaginal and rectal explorations are also necessary. By all these methods we can be very certain as to whether a complete operation through the vagina can be made. And yet, in our last case of ruptured tubal pregnancy we made the mistake, and had the chagrin of being unable to remove the larger part of blood through the bulging cul-de-sac of Douglas, and had to do a section above. Kelly has called attention to the absence of hemorrhage during and after the vaginal operation. He has also invited us to notice that removal of pelvic viscera is not so common in the vaginal as in the abdominal operation for ruptured tubal pregnancy. This may or may not be advantageous. It is quite possible that Fallopian tubes that have produced tubal pregnancy and have ruptured, may be of future benefit to the patient. *Per contra*, may not their retention be a source of danger to the life of the individual, either of repeated tubal pregnancy or of sufficient diseased condition to cause future prolonged misery of that life. or even worse. This matter is still *sub judice*. On the whole, the writer feels that it is better to favor the course of leaving as much of the pelvic organs as possible, and to allow these organs an opportunity to be restored to a functionating condition.

Nature sometimes does wonderful things in this direction and we should allow her the necessary opportunities. We can feel sure the tube has recently been permeable else it could not have been pregnant. The writer has done six cases by the vaginal route, all of which have promptly recovered, and in none of them has any severe pelvic trouble followed. We should also bear in mind that many of these patients are in a condition so bad that they stand mutilation very badly, and therefore should not be made to bear any traumatism that can possibly be avoided.

The histories of the writer's cases are as follows:

Case 1.—Mary, colored, 23 years old, was referred to me and sent to Columbia Hospital Sept. 17, 1894. Her history was as follows: She had been married two years and was said to have had two abortions, the last of which had occurred Aug. 15, last, and was of a fetus of six weeks' development. As her menses were regular she was sure she had been pregnant in August, but the doctor told me, after careful questioning, that he had been called after the fetus was supposed to have been passed, and she was yet having considerable flow and pelvic soreness. She had not been well since the so-called mis-carriage, and had been flowing at intervals during the interim.

An examination revealed a slightly enlarged uterus, high and fixed anteriorly; abdomen prominent, a firm swelling in the right inguinal region that extends down behind the uterus to half way down the posterior vaginal wall; here it is boggy to touch and has the feel of an abscess pointing to open; the lowest point of the accumulation is thought to be most fluid. From the history, ruptured tubal pregnancy was diagnosed, but the physical examination led us to also suspicion the presence of pus; this was added to by the patient telling us she had been having chills and sweats.

Three days after admission the abdomen was opened and dense adhesions to the abdominal wall found; the pelvis was filled and the color of the tumor indicated blood rather than pus; closed incision and placed patient in lithotomy position. The soft lowest point of the mass was opened through the vagina with scissors, and through the opening escaped a quite large quantity of dark, fluid blood. The opening was enlarged and about two quarts of blood clot, fetal membranes and fluid blood removed. The cavity thus made extended behind and to both sides of the uterus and up to above the sacral promontory. It was irrigated freely and drained. Both appendages were found enlarged and in the adhesions, but were not interfered with in any respect. Menstruation occurred normally two weeks later while in the hospital, and on October 25, a small mass was yet present on either side of the uterus. However, as she was feeling very well and had no pelvic pain whatever, she was sent home to return if trouble occurred. The husband of this patient during the past winter told us she has had no pelvic trouble since.

Case 2.—Mrs. B., white, mother of two children, the youngest being 5 years old, was seen in October, 1895. She had not missed a period, but from various symptoms she suspicioned pregnancy and abortion, as she passed some membrane from the uterus, accompanied with great pain and some hemorrhage ten days before. An examination found the uterus slightly enlarged and softened and the cervical canal patulous. An examination demonstrated the presence of a slightly movable and nodular mass behind the uterus and ectopic pregnancy was diagnosed. The same day she was etherized and the uterus explored. It was found empty, but three inches in depth. The pelvic mass was now opened by a small transverse cut through the vaginal wall behind the uterus and its contents evacuated. It was principally coagulated blood and a small amount of membranes; a tubal cast of blood was removed; no fetus was found. As both appendages were high and adhered, I did not attempt to loosen or remove them. The sac was irrigated with boiled water and packed firmly with iodoform gauze.

The packing was removed next day and the cavity irrigated; no evidence of hemorrhage was present and no packing was inserted; vaginal douches of 1 to 5,000 corrosive sublimate solution were daily employed for nearly three weeks, when she was considered well.

Case 3.—Mary C., white, single, 23 years old, was seen at her home June 8, 1896. She had missed one period but seemed to attach no significance to that fact, pretending to have gotten her feet wet during her last period. She was very pale and suffering from severe pain in the pelvis and rectal tenesmus. It was only after considerable difficulty that her consent to a vaginal examination was secured. Upon introducing the finger into the vagina it was found to be quite capacious and the cervix slighty lacerated on the right side. Behind the slightly enlarged uterus was a boggy tumor that did not seem to extend much above the symphysis and was most marked on the left side. Upon withdrawal of my finger it was found to be covered with blood. She then acknowledged she had been treated instrumentally by an abortionist, fearing she was pregnant. This had occurred a few days before, after which, on reaching home she had gone to bed on account of severe cutting pains through the pelvis; this was soon followed by a gush of blood from the vagina, and bleeding had continued at intervals nearly all the time since.

Next morning she was chloroformed and a small opening made into the mass behind the uterus through the vaginal vault. A few ounces of thin blood and some clots poured out through this opening and a finger removed more of the same material, together with some shreds that resembled fetal membranes, and felt a roof to the cavity. The left tube was found to be low, about an inch in diameter, and in its wall was found a small opening, through which was felt protruding thin membranes. These were pulled out, and as no bleeding seemed to be going on the sac was washed out and packed gently with iodoform gauze. She made a perfect recovery and was out of bed on the fourteenth day. No fetus was found, but to the naked eye the character of the membrane was unmistakable.

Case 4.—L. L., colored, 22 years old, married, admitted to Columbia Hospital Sept. 20, 1896; had had two children, the last two years before and no abortion: menses began at 18 years of age, were regular, of fair quantity and slightly painful. The last two periods had differed however, the first being very *scant and of short duration, while the last had been continuous* during the four weeks previous to admission. She complained of severe pain in the lower part of the abdomen and of great weakness. An examination revealed blanched mucous membranes, great emaciation, a very frequent and small pulse and rapid respiration. A mass was found extending from the pelvis behind the uterus, upward about 7 cm. above the pubes, very sensitive to the touch and slightly fluctuating. The uterus was found to be slightly enlarged, fixed anteriorly and above its usual plane. The lower part of the mass was quite soft and encroached on the vagina.

September 24 vaginal puncture was made and two liters of solid and fluid blood with fetal membranes evacuated. Free irrigation of the cavity was done and as no bleeding was present, nothing further was deemed necessary. The left appendage was found very much enlarged and ragged, but was not disturbed but packed for a few days with iodoform gauze. Two weeks later she sat out of bed and was allowed to go home one week later, though the left tube was still enlarged.

Case 5.—Mrs.— had had four children and one abortion, but during the four years previous to this illness had not been pregnant. She had missed one period but did not consider herself pregnant, as no symptoms of her former pregnancies had been present and menstruation had not been regular. She had been working very hard one day arranging furniture, and was uncomfortable on going to bed. During the night she awakened with great pain in the pelvic region and felt very *faint. Thinking she had worked too hard and that it was nec*essary to rest, she did not arise in the morning. Later in the day she felt cold and chilly and sent for the writer. I was absent from the city for the day and she did not call another physician, and did not send again for me until two days later. On Sept. 28, 1896, an examination revealed the uterus to be high in the pelvis and to the front; behind this in the cul de sac was a mass, that resembled a pus tube ready to rupture into the vagina. This sac was mistaken for a pus collection, and later in the day, with the assistance of her husband, she was chloroformed and the sac opened through the vagina. To my surprise no pus came away, but instead about eight ounces of fluid and coagulated blood. As the top of the sac seemed to be firm and the appendages could not be easily palpated, they were left undisturbed and the cavity emptied of clots and a material resembling early fetal membranes. The cavity was quite firmly packed, as there was a slight tendency to hemorrh- The cavity was again emptied on the third day and lightly ked. She made a good recovery.

se 6. Mrs. H–, white, 27 years old, seen in consultation hevy Chase, Md., January 7, 1897, with Dr. E. A. Sell- sen. History: Married one year, menstruated regularly l November 15, when flow not appearing at time took a box hichester's pennyroyal pills, twenty in number, during e days, and on the 24th of that month began flowing pro- ly and with extreme pain. This was *the first painful* men- ation she had ever experienced. The pain was so severe she collapsed, and it lasted all night and well into the next . She remained in bed several days, suffering with vomiting great exhaustion. At the time I saw her the pulse rate but 9[illegible], and feeble, and the temperature 102. The uterus slightly *enlarged and pushed high to the left* and front by a mass to the right that was slightly movable and fluctuating; it was rounded and, according to Dr. Sellhausen, gradually increasing in size. Its contents were thought to be blood from a ruptured tubal pregnancy, or pus. Advised operation, and as conveniences were not at hand it was thought best to move her to a hospital, which was done the next day, after her temperature was found to be 103 degrees. January 9 opened through vaginal wall into tumor and evacuated the cavity that extended across pelvic cavity. Still higher to the right was found a cyst about three inches in diameter that was thought to be an ovarian cyst and was evacuated as well. Irrigated with [illegible] solution; after removing considerable débris [illegible] thought *to be* fetal structures, packed with gauze. [illegible] fell from 11[illegible] on the morning of the operation gradually [illegible] on the fourth day, and the temperature took a [illegible] from 103.5 degrees. She made an uneventful [illegible] and left the hospital within three weeks.

Conclusions.—In concluding we would urge:

1. That the vaginal route is preferable for operation for ruptured tubal pregnancy when the hemorrhage has ceased or is slow, the escaped blood limited to the pelvic excavation, and especially if a limiting diaphragm has formed above it.

2. That the vaginal route is freer from shock, is less liable to permit infection and furnishes better drainage.

3. That there is less liability to the removal of the adnexa than when the abdomen is opened.

4. That the period of convalescence is shorter and devoid of many of the usual complications of abdominal section.

1404 H Street.

VAGINAL SECTION.

Presented to the Section on Obstetrics and Diseases of Women, at the Forty-eighth Annual Meeting of the American Medical Association, at Philadelphia, Pa., June 1-4, 1897.

BY LEWIS SCHOOLER, M.D.
DES MOINES, IOWA.

By the term section is meant an ample opening for the extraction of the fetal membrane, as well as the fetus itself, if present. To Recamier is awarded the piority, although *unintentional on his part.* He, *no* doubt being impressed with the teaching of the day with reference to a hematocele, which was, but a short time ago, the same as the teaching in regard to peritoneal and intraperitoneal affections. To see why this should have been so one has but to recall the unfavorable statistics with reference to many surgical affections. Lister had not then promulgated the advantages of asepsis and antisepsis. Bacteriology had not then become a science. In fact, the profession was far more ignorant regarding the causes of disaster than they are now.

The science of diagnosis of pelvic troubles was crude in the extreme. Crude for lack of accurate pathology; and while the strides toward accuracy in this respect have been great and rapid, the student of twenty years ago must often feel chagrin when he recalls how much of what he then called knowledge but now knows that it was not in reality useful knowledge, for the advancement of the age has forced him to discard it for the reason that all of our pathology was obtained from the dead subject. Today clinical observation with operations during all stages of inflammatory processes, from the earliest to the latest, has furnished the pathologist with an abundance of material and has also familiarized the operator with the microscopic aspect, which of itself is of untold value.

Two thousand years of empiricism and conservatism had accomplished little or nothing. Human suffering and surgical advancement demanded something more radical and more definite as well as more successful.

Working along these lines, in a variety of cases, principles were evolved that have completely revolutionized the practice of the older gynecologists. The gain to mankind in general and to womankind in particular *can not be computed. That errors have been* committed by *ambitious and unqualified persons* is apparent, and may have retarded scientific work in some quarters; in others it had but helped to emphasize the need of well-defined principles.

Most of us were taught that diagnosis of extrauterine pregnancy was an impossibility and as there was no treatment the diagnosis was no great loss. Today we diagnose with remarkable accuracy, operate without fear and save the lives of many women. We have learned how to prevent sepsis and to control hemorrhage; we have learned that the evacuation of clotted blood does not retard, but with proper precautions hastens recovery.

Having arrived at this point it would seem that the remainder of the distance to be traveled by the gynecologist was not beset with many difficulties. The route, however, divides right here, and what may be the proper course in one case may be decidedly dangerous in another. The infected and the uninfected, the complicated and the uncomplicated, each requires investigation. Two avenues are open, neither is safe, absolutely, as a routine. The advantages of the vaginal route are to be found in the cases where pus abounds, and where contamination of the abdominal viscera would most certainly occur were the collection attacked by that route. The pus is easily evacuated without the risk of shock, hemorrhage or contamination, and with the minimum of mutilation. Danger of infection from irrigation or mopping is not even a possibility. Breaking up of adhesions, causing bleeding, necessitating clamps or ligatures, is greatly lessened, as in the great majority of cases no foreign body is left in the wound except temporarily. In well-marked uninfected collections, with the membranes adhering to the ruptured tube, it is also possible to remove them with little or no trouble by this method, and when so done the operation, even here, possesses advantages, although it is in these cases that the abdominal method is frequently to be preferred for the reason that when the abdomen is opened the placenta may be safely removed and the hemorrhage controlled. The ligation of all bleeding vessels is done under the guidance of the eye. The operation is short and should not be followed by shock or secondary hemorrhage. The latter is an accident which sometimes occurs after the vaginal operation, requiring a laparotomy at a later date, as happened in one of my own cases. Circumstances of this kind have induced operators to recommend and to practice being prepared to make a laparotomy in the same case where the vaginal method fails or is unsatisfactory. It may be said, however, that where the vaginal wall is incised and irrigation and drainage used nothing is sacrificed by the operator. That the generative function is unimpaired, save in so far as it is interfered with by the cause which requires surgical interference; whereas by the abdominal method laceration and ligation may necessarily cause the sacrifice of an ovary or a tube.

Adhesions of intestines to uterus, tube or ovary may be greatly enhanced, while by the vaginal method it would not be at all influenced, this being, in some cases, of inestimable value afterward. It is urged by some that hernias are equally as frequent in the vagina as in the abdomen. This I do not believe: though it would not be strange should it occur oftener than it does. Healing by first intention and accurate approximation of incised tissue are not to be thought of in the vagina. Healing by second intention is alone expected and is often delayed and hindered in order to be sure that all the cavity is drained and obliterated, while in the abdomen in all properly selected cases the edges of the wound are carefully approximated and closed without drainage. The peritoneum and the different layers of tissue may be sutured separately, if deemed of advantage, though to my mind it is far from being essential. It is in these cases that we expect the greatest strength in the wall after a section. Where infection already exists or accidentally occurs at time of operation or where drainage is a necessity, a portion of the wound usually heals by second intention, just as does the wound in the vagina; and here my observation teaches me that the abdominal hernias exceed the vaginal. Ligatures themselves, when of silk, sometimes fail either of absorption or encystation and become a source of infection, locally causing abscesses and sinuses, necessitating an operation for their removal, an operation, too, no less formidable than the first and sometimes with greater danger of infection.

It is within the experience of every operator that the virulence of pus differs within the widest limits governed by age and the character of the germ. Few are there who have not opened the abdomen and found pus in abundance, which after its removal seemed to leave no deleterious effect behind, while *vice versa*, a small or recent collection was possessed of such virulence that no amount of asepsis, by irrigation or otherwise, seemed to lessen its force in the least. Could we determine this in advance it would in many instances be the governing factor in not only the cases we are now considering but with many others with which we have to deal.

The strongest objections urged against the vaginal operation are that it is not a definite operation, that damaged tissue is necessarily left behind and that bleeding vessels are unseen and may produce disastrous results, that the conception does not take place in the tube and that the product is not always found between the folds of the broad ligament, and when found free in the abdominal cavity may even glide beyond the reach of the operator, or if within reach is found to have reached too great development to permit extraction through so limited an opening.

Again, it is claimed in pus cases (and it is certainly admissible to consider them here, as pus sometimes present is a complication and again through mistakes in diagnosis, is found to be the identical condition with which we have to deal), that a cure is not effected and that abdominal section is at last the only source of relief. This is claimed to be the observation of many able operators of large experience.

In other cases it is claimed that a small amount of relief is obtained and the woman suffers on in silence rather than undergo another operation, while the operator classes the cases among the cured. How much of this is true is difficult to estimate. That in some cases palliation is the only result is doubtless true. The same may, however, be said of abdominal operation, not only when performed for this but for many other afflictions. While the more radical operation has the advantage, so far as definiteness is concerned, it is too radical sometimes. Important organs are too frequently sacrificed. The swing of the pendulum is already more conservative and the assertion that it is cowardice instead of advancement will have to be supported by argument and by facts capable of demonstration before the position taken by able and experienced gynecologists will be yielded. Since human happiness is the end sought by all it behooves us all to lay aside all prejudice and carefully record our observations only after a sufficent length of time has elapsed to insure their reliability. Preconceived theories are of no value unless supported by facts, and beliefs are of no value unless they are capable of demonstration.

If after the lapse of time the vaginal operation for extra-uterine pregnancy is found to relieve a large percentage of cases, with safety and dispatch, it will take its place as a legitimate life-saving operation. If not it deserves no better fate than to be forgotten by gynecologists, and the sooner the better.

Byford has recently reported 162 cases of vaginal section with only five deaths, and three of these cases should not have been operated upon by this method.

DISCUSSION ON THE PAPERS OF DRS. PRICE, BOVEE AND SCHOOLER.

Dr. J. HENRY CARSTENS of Detroit—These papers cover the ground of extra-uterine pregnancy pretty thoroughly, although Dr. Bovée and Dr. Price do not seem to agree. I think they are really both right. I would not like to say that we should do one operation always. Dr. Schooler and Dr. Bovée admit that when we have acute cases with active hemorrhage, the best thing to do is to open the abdomen, ligate the artery and then we have no trouble. When we have a case like Dr. Bovée speaks of, where the active symptoms have ceased, where the tube has dropped down, has become firmly adherent everywhere, it is reasonable that we should puncture the cul-de-sac, let out the blood and allow the placenta to gradually dissolve and come away with the discharges without much shock or danger to the woman. That is my method of practice. I wish to most emphatically dissent from the doctrine advanced by Dr. Price, that in case of extra-uterine pregnancy which has advanced to the fourth or fifth month, we should not take away the placenta at once. I hold that this is very dangerous and serious and very bad practice. If we have a case of pregnancy only three months advanced, we can shell out the whole thing without trouble, ligate the pedicle and close up the abdomen. When we have a six months' pregnancy with a large sac adherent to the left side of the diaphragm, the hemorrhage we get in such cases is frightful, and the woman is in great danger, in the hands of an ordinary man at least. She would not perhaps be in such danger in a hospital in the hands of Dr. Price, where he has all the facilities, but in the hands of a less experienced man and in a private house, it is dangerous practice, and it has been so proven over and over again. If the records of cases of this kind where men attempted to do too much could be collected, we should find that the mortality is frightful. I know of a number of cases that have not been placed on record. We hear only of the cases that recover. It is better practice in my judgment in cases of extra-uterine pregnancy at the sixth or seventh month to simply open up the sac, take out the fetus, stitch the sac to the external abdominal wall and let the placenta dissolve. If it is done aseptically you will have no trouble. This is the best practice for the average general practitioner who has to do this operation in emergency cases. In exceptional cases the experienced surgeon may safely take out the sac.

Dr. L. H. DUNNING of Indianapolis—In reference to ectopic gestation, I am very much of the opinion expressed by Dr. Carstens, that there is a great deal of truth in the statements of these gentlemen who oppose each other in their methods. Yesterday I stated that it was my privilege to see two old cases which ruptured early, and I saw them four or five weeks after rupture. The history was clear, yet months had elapsed since rupture had taken place. A large hematocele had opened through the vagina, and the patient made an excellent recovery.

I want to say a word here relative to the experience of Dr. Price regarding broad ligament pregnancy. I believe he has made the statement that he has never encountered a case of broad ligament pregnancy, and that he disbelieves in the existence of this form of pregnancy. I do not believe that he wishes to convey such an idea, and yet we should have this thought in our minds in dealing with every case at full term. Here are two cases which demonstrate beyond peradventure, that broad ligament pregnancies do occur. In the first case, because the picture of dissections made from the frozen subject shows the placenta was attached beneath the abdominal walls between the muscular coat and peritoneal coat. I have myself encountered one case which I operated on two and a half months after labor and enucleated the fetus and sac without rupture, the same as we would enucleate an intraligamentous cyst retroperitoneally. The placental attachment was in the tube. It was three quarters of an inch thick, distinctly separated from the broad ligament covering and might have been removed without trouble. As it was we enucleated the fetus and sac without hemorrhage two and a half months after labor. The only point I contend for is that we must recognize the fact that there is such a thing as broad ligament pregnancy.

STUDIES IN GYNECOLOGY FROM THE SERVICE OF THE WOMAN'S HOSPITAL OF PHILADELPHIA.

Presented to the Section on Obstetrics and Diseases of Women, at the Forty-eighth Annual Meeting of the American Medical Association, at Philadelphia, Pa., June 1-4, 1897.

BY ANNA M. FULLERTON, M.D.

PHILADELPHIA, PA.

My paper does not pretend to be a contribution to the most interesting and valuable subject of surgical gynecology but rather a plea for what may be termed preventive gynecology, to which perhaps we have given too little heed in the past.

Not that I would in any way decry the brilliant and skilful results attained by surgical gynecology in this day, for it is too true that diseased conditions affecting the pelvic viscera very frequently result in the production of organic lesions which induce chronic invalidism and render the functional activity of the generative organs a menace to the health and even the life of the patient. Too often, however, the operator himself realizes that in the removal of diseased pelvic organs he is but cutting away, as it were, dead twigs and branches from a plant which has a worm at the root. It is not a matter of surprise, therefore, that when the same social conditions must continue which have originally caused disease, a speedy recurrence is found of the manifestations of ill health. It has not been uncommon in my experience, after having removed pus tubes for a patient, to have her return suffering from an acute attack of gonorrheal cystitis, endometritis or vaginitis. To insure against the recurrence of an endometritis, at least, it is always best I believe in such cases to amputate the uterus at the same time that the appendages are removed.

Practically, the performance of these very radical operations upon the pelvic organs unfit a patient for the marital life, and since two-thirds of all patients operated on for pelvic diseases are women who are or have been married, the decision as to the absolute necessity for any operative procedure is one requiring a very careful judgment.

So largely is the health of a woman affected by her emotions that any cause for unhappiness induced by the changed conditions of her life may seem to make her last state worse than the first. For these reasons it is my ardent hope that we may look in the future to the fuller development of the constructive processes of our art, the making of healthy women.

How rarely do we find in the special hospitals for the treatment of the diseases of women, any tolerance of the so-called palliative measures for the relief of the pelvic disease! Yet there is a time in the development of many of these when they are not beyond the pale of hope. There is no better vantage ground for a study of woman's needs than that afforded by such a hospital as that with which I have been connected for many years, the Woman's Hospital of Philadelphia, with its large obstetric and gynecologic service. Here opportunities for careful study may be obtained, the constitutions and habits of life of patients observed and such investigations made as to cause and effect in the production of disease as can not fail to bring much enlightenment.

In reviewing the records of the Woman's Hospital of Philadelphia, during the time of my incumbency as its physician in charge, from September, 1886 to September, 1896, I found that among nearly forty thousand cases treated in its wards and dispensary over 41 per cent. were inflammatory disorders of the pelvic organs, mainly septic in origin, puerperal or gonorrheal; 27 per cent. were displacements with their attendant complications; 14 per cent. were functional disturbances, mainly due to constitutional causes and arrest of development; 7 per cent. were neoplasms and over 10 per cent. lacerations resulting from childbirth.

In making a study of the conditions which might be regarded as causative factors in the production of the graver forms of pelvic disease I analyzed 236 cases of major operations occurring in my own service. Forty-two being hysterectomies, twenty-one ovariotomies, twelve cases of extra-uterine gestation and the remainder chiefly cases of diseased appendages, including thirty-three cases of pyosalpinx.

In 40 per cent. of these the morbid condition seemed to be directly traceable to a puerperal origin; in 15 per cent. there was a hereditary predisposition to tuberculosis; in 12 per cent. a specific taint; in about 14 per cent. simple inflammatory conditions appeared to be the result of exposure or trauma; in 5 per cent. there was imperfect development of the pelvic organs; in 5 per cent. also, persistent uterine displacements; in another 5 per cent. anemia appears to have been the most prominent factor, and in 4 per cent. malignant disease. The facts connected with these figures are in themselves suggestive of the measures to be taken which might obviate much of the suffering. Hospital experience constantly goes to prove that the woman of modern times is inferior in physical resistance to the women of primitive times.

This physical deterioration, although in part the result of the process of evolution by which nature decrees that like shall produce like and that the sins of the fathers shall be visited upon the children, is also the result of an unnatural environment and habits of life which threaten, if persisted in, to result in the extermination of the human race.

The especial manifestation of this inferiority in the growing girl consists in a condition of nerve and muscle atony which greatly weakens her powers of resistance. The pelvic maladies resulting from this condition are arrest of development, displacement and inflammatory involvement to which all weakened tissues are liable on slight cause. Necessarily these conditions tend to disorganize the menstrual life of the young girl and sow the seeds of future calamity. A condition of post-menstrual subinvolution is commonly found which is aggravated after each period of menstrual congestion and results in changes of structure in the tissues of the pelvic organs. The indications, therefore, are for a radical and rational treatment of these abnormal tendencies. I do not agree with the teaching that there should be little local treatment given such cases, nor have I found treatment properly carried out to be demoralizing. The relaxation of the vulvar and vaginal tissues induced by a catarrhal condition of the mucous membranes, as a rule, renders local treatment easy and painless. The use of cocain in any case renders it quite manageable.

Local treatment is only a temporary aid to the restoration of normal conditions. The most vigilant and pains-taking effort requires to be directed to improving the tonicity of the uterine supports as well as of the muscular system generally, improving the quality of the blood and combating any especial dyscrasia. The usual tendency to inactivity of the bowels, bladder and skin must be overcome. Before beginning any treatment I insist on such arrangement of the clothing as shall entirely remove all pressure from the chest and waist. This can be done perfectly well without rendering the clothing unsightly or unattractive and is absolutely necessary to the attainment of satisfactory results. In an article written some time ago by Dr. Kellogg on "The Relation of Modern Dress to the Pelvic Diseases of Women," he has admirably shown, by a series of experiments, the effect produced by constriction of the waist upon the mobility of the pelvic organs and on the tonicity of the abdominal muscles and uterine supports. The round ligaments he has demonstrated to be the chief agents concerned in the maintenance of the uterus in its proper position, their power being dependent on the muscular fibers which they contain. Any fixation of the pelvic organs tends in time to produce loss of contractile power in these uterine supports, and as a result we have displacement of the organ or the beginning of a series of ills. The clothing should always be worn sufficiently loose to enable the patient to exercise the abdominal muscles. The removing of all waist bands and the adjustment of the skirts in such a way that their weight is borne by the shoulders facilitates this purpose.

After the matter of clothing has received proper attention I teach the patient how to practice abdominal breathing and give her a series of exercises for strengthening and developing the abdominal muscles. The judicious use of the bicycle is a great aid to overcoming loss of nerve and muscle tone. Even when marked uterine displacement exists I do not prohibit this exercise, but only permit it while the uterus is maintained in proper position by means of tampons or a soft rubber pessary, the presence of which even in the case of falls would have little or no ill effect.

Should a marked catarrhal endometritis exist, it is sometimes well to precede all other treatment by a curettement of the uterus under proper precautions. Such treatment as the above, carried on for weeks and even months with the growing girl has, in my hands, proved fruitful of most excellent results, and has been of great advantage when persisted in even after this period.

The weight of the patient's trunk being borne by the saddle of the bicycle, she can take much more exercise with less exertion than she could if she attempted to walk. In older women, with relaxed vaginal outlet, I have found that I have gained much by teaching them how to introduce a sponge daily into the vagina in such a way as to lift the uterus into proper position. A soft silk sponge of proper size is selected and made into a tampon having a string fastened to it, by which it may be withdrawn. The patient is instructed to keep this over night in carbolized water, after having thoroughly washed it out after its withdrawal, with castile soap. Before its introduction, it is annointed with boroglycerid, and as it needs to be carried up in the pelvis to a point farther than the finger can reach, she is instructed how to use a thick glass rod, such as may be obtained at any drug store, to carry it well into the hollow of the sacrum and behind the cervix uteri. The knee-chest position facilitates its adjustment.

The same sponge is only permitted to be used two weeks, when a new one must be obtained. Patients unable to wear pessaries because of peri-uterine inflammation or tender ovaries have found this treatment very acceptable. It is only permitted to be carried out under strict medical supervision.

Unhealthy conditions of the pelvic organs brought about previous to marriage illy fit a woman for child-bearing, and as a consequence, we find the following perversions of the normal phenomena associated with child-birth:

1. During pregnancy, a tendency to the early loss of the product of conception, owing to a diseased condition of the endometrium.

2. When this does not exist, a tendency to the prolongation of the period of gestation, the result of the atonic condition of the uterine tissues and of the abdominal walls, which thus more readily submit to overdistension.

During labor we find dystocia caused: 1. By physical exhaustion, the result of neuromuscular atony, which renders uterine contractions inefficient.

2. By the mechanical hindrances to the progress of labor produced by undue size and ossification of the fetal head, this being undoubtedly attributable in large part to the physical inactivity of women in civilized life during pregnancy.

During the lying-in period we have: 1. The lengthening of the time required for the process of involution, also frequent subinvolution. This condition of puerperal subinvolution, as does that of menstrual subinvolution, predisposes the uterus, upon the action of all causes of pelvic congestion, to take on structural change. A second perverted phenomenon of the lying-in is the imperfect performance of the function of lactation. A third is what may be termed a subinvolution of the abdominal muscles. The effect of this relaxation of the abdominal walls upon intra-abdominal pressure and its relation to prolapses and displacements of the pelvic organs is a matter of great importance.

All these conditions may be averted or modified by judicious treatment. Without dwelling unduly on the methods to be followed, I should like to mention the effect of bicycle riding as persisted in by two patients during their pregnancy. The one who had always suffered considerably from delay during labor, had the shortest and easiest delivery she had ever experienced and a more satisfactory convalescence. The other is still riding her wheel during the last month of gestation. Fearing she might injure herself by a fall I tried to dissuade her from doing so, but after a few weeks she begged me to allow her to resume the exercise, saying that it tired her so much less than walking and prevented her from getting melancholy. Both patients live in a suburban place and hence are not subjected to the accidents so common in crowded streets.

When a contraction of the pelvis complicates the condition of things in a patient of weakened muscular power I give especial attention to aiding the first stage of labor. In the maternity wards of the Woman's Hospital I found about 14 per cent. of the patients to have contracted pelves. Including among abnormal cases those of faulty inclination, the number reached fully 20 per cent. This is perhaps owing to the large proportion of foreigners delivered in our obstetric wards. The generally contracted pelves were found to at least double the number of simple flat pelves. The average contraction was not of a high grade. In the simple flat pelves the conjugata vera varied between 8 and 10 cm; in the generally contracted between 9 and 10 cm.

The management, *par excellence*, of moderately contracted pelves is, to my mind, the induction of premature labor. The advantages of premature delivery to the mother are owing to the diminished head pressure; hence the rare occurrence of lesions of the genital canal. I have rarely found it necessary to induce labor before the thirty-sixth week. The aid of the *couveuse*, or hatching-cradle, is very appreciable in the management of premature infants in our maternity. The fetal mortality from all causes during the period covered by my investigations was 4.3 per cent. On the occurrence of uterine inertia during labor, when it could not be overcome by suitable tonics, artificial delivery was resorted to, the presenting part not being permitted to remain stationary at any one point long enough to endanger the maternal tissues by pressure.

During the lying-in, when the lochia rubra persisted for a longer period than was normal, I made an examination to discover the cause. Was there a tendency to uterine malposition, this was kept corrected. A possible hypertrophied condition of the endometrium treated by gauze packing or gentle curettage, which served also to stimulate uterine contractibility. Hot douches were employed and the patient kept in a reclining position longer than was usual. Difficulties with regard to lactation can largely be met by a judicious management of the patient, especially with reference to diet during pregnancy.

The methods just described have proved most satisfactory in our hands in the management of the obstetric work of the hospital. The maternal mortality was less than 1 per cent. About 19 per cent. of the cases required operative interference at full term. The operations included Cæsarean section, the Porro operation, symphysiotomy, forceps deliveries, versions, the management of breech deliveries, craniotomy, embryotomy and the induction of premature labor. I have found in my work that whenever I was able to reach a woman's understanding, getting her to co-operate with me in the measures intended for her relief, I have had little difficuly in carrying such measures into effect. I therefore believe that it is in the education of women to a proper appreciation of physiologic laws and of the virtue and dignity of true wifehood and motherhood as controlled by these laws, that we will find the most powerful factors in the work of reform which we hope may result in her physical restoration and in the production of a healthier generation of human beings as her offspring. At the close of a lecture given by myself recently on the subject of personal hygiene, to a large class of young ladies in one of our fashionable schools, I had a striking illustration of this. One young lady among several grouped around me said most earnestly: "Doctor, if you have been doing everything all wrong before the age of 20 is there any chance for you to be set right afterward?" I would close with a query addressed to the members of this Section of the American Medical Association: Do we as conservers of the health of women so influence the education of the young men and the young women of our day as to teach them how to live for healthy parentage.

DISCUSSION.

Dr. Howard A. Kelly of Baltimore said in regard to the contagious diseases, such as typhoid fever, diphtheria, etc., that we have learned a great deal in the way of prevention, and could readily prevent these diseases if matters were entrusted to physicians entirely, but politics entered here and our municipal authorities made scientific discoveries more or less futile in this country. In the matter that Dr. Fullerton had brought before the Section today, it was in the hands of physicians to mold very largely the future generation, to carry out those plans which we know will result in the prevention of disease, and in producing better women and a better race in the next decade. This subject had for a long time been prominently before his mind in connection with gynecologic work. It was a question which confronted him almost every day of his life. Prevention might be classed under two heads. In the first place, prevention which anticipated disease. In the second place, prevention which attacked disease in its earlier stages and prevented graver consequences, such as death, or the necessity of graver operations later. Under the head of anticipation he classed the treatment of the young girl, saying her education began with her mother or in the cradle. The education of our girls was in his opinion largely wrong. They were confined too much; they did not get sufficient exercise, and at the developmental period the abdominal corset came in. He has difficulty with his patients on account of wearing corsets. The corset prevents proper expansion of the chest, and in doing this it likewise prevents the proper development of the abdominal walls. Then, too, in the line of prevention he would urge on the profession at large painstaking attention to all symptoms. Physicians in general were too apt to pass over what seemed to be slight symptoms in women. Anything which did not cause a great deal of discomfort they readily overlooked, and sooner or later the woman came back, when the physician was forced to examine her. Discharges should be carefully investigated, notably excessive hemorrhage or lochial discharges, and if serious, treated. Pain, if persistent, should be investigated and a minute painstaking examination made under an anesthetic, if necessary. Another important means of prevention was cleanliness in caring for obstetric patients. The physician could not do better than to go to every case of obstetrics with a white suit on, not that the suit itself did anything in particular, but it impressed on the physician that the attitude toward the patient was different from that which he holds to any of his other work. Furthermore, it was of the utmost importance to observe greater caution in personal cleanliness, in scrubbing and cleaning the hands, etc., and in this connection the kind of scrubbing brush used in most clinics in Philadelphia and other cities was little better than a wash rag. Soft scrubbing brushes were worse than useless, and surgeons were deluded into the idea that they were doing something with nothing. With reference to gonorrhea, which is a frightful source of many ills, we needed better morals among men; we wanted the same rules for men as for women. Both should be treated on the same principle. When we give our sisters the same rights of license and indulgence that were given men we would have less ills to complain of and fewer diseases to treat in married women. An important preventive, then, of disease was morality.

Dr. William A. Fisher of Philadelphia said that Dr. Fullerton's paper indicated that the gynecologist should be a good all-around practitioner. Disordered conditions of the pelvic organs did not always depend on diseased conditions of those organs, but in some cases on disordered conditions of the liver, of the blood, of the heart and so on, so that it was necessary to bear in mind as regards the future dependence of organs the fact that in woman the pelvic organs dominate her whole being. We should consider in the study of symptoms connected with the pelvic organs the temperament of the patient, whether or not she is of the lymphatic, nervous or plethoric type. All these had an important bearing on symptoms in pelvic troubles. One woman with a slight retrodisplacement of the uterus might suffer excruciating pain, while another with a decided retrodisplacement would suffer but little, simply because of the difference in the nervous organization of the two women. Exercise is very important in the treatment of disordered pelvic conditions. By judicious exercise we cause an increased amount of blood to the surface and body and relieve congestion of internal organs. The circulation in the pelvis is largely carried on by respiration and inspiration, and during the act of each respiration and inspiration we have a rise and fall of the pelvic diaphragm and with it maintenance of the pelvic structure. In order to keep up proper pelvic circulation it is necessary for women to have their clothes loose about their waists. Furthermore, in so far as the uterus is concerned, we know that women are unwell about one-fifth of the time and they do not take extreme care of themselves at this particular time. I refer to the time of menstruation. They expose themselves to cold and damp. This brings about chilling of the surface and internal congestion, and at the time of menstruation may give rise to dysmenorrhea, and this frequently repeated may result in the production of pelvic disease. The skin, as a very important excretory organ, is often forgotten by practitioners in general. The skin in its active condition throws off excrementitious products, and when it is in an inactive condition we have the accumulation of toxic materials that should be thrown off by it. If there is pelvic disease existing or a tendency to it we may have a localized expression of this want of activity of the skin in certain conditions of the pelvic organs, etc.

Dr. Milo B. Ward of Kansas City, Mo.—I would like to ask Dr. Fullerton the effect of bicycling on girls.

Dr. Fullerton—Unless there is considerable pelvic disease I consider bicycling a great aid to the development of the muscular structures of girls.

Dr. Ward—How do you account for the fact that women who ride bicycles can not walk; that is, they are too weak to walk?

Dr. Fullerton—I do not think this would obtain after they have used the bicycle for some time. There is really less fatigue from using the bicycle than in active walking. After the muscular system has been developed, I believe a woman who learns to ride a bicycle can walk farther than her sister who does not ride a wheel.

Dr. A. H. Tuttle—I would like to ask Dr. Fullerton if she prescribes any regulation dress for young ladies who use a bicycle?

Dr. Fullerton—Always. I do not permit them to ride a bicycle with a corset.

Dr. A. E. Miller of Boston—I would ask Dr. Fullerton if she has ever met any bladder difficulties arising from bicycle riding, as for instance, irritable bladder?

Dr. Fullerton—Only in those cases where the women have not selected and adopted a proper saddle. If they use an improper saddle it will cause discomfort in more than one way. If proper attention is given to the performance of the functions, to evacuation of the bladder and bowels, to dress, etc., I do not believe any injury can result from bicycle riding.

THE INJURIES OF PARTURITION, THE TIME, METHOD AND REASONS FOR THEIR REPAIR.

Presented to the Section on Obstetrics and Diseases of Women, at the Forty-eighth Annual Meeting of the American Medical Association at Philadelphia, Pa., June 1-4, 1897.

BY A. H. TUTTLE, M.D., S.B.
CAMBRIDGE, MASS.

In May, 1893, I was called to Milford by Dr. Wm. J. Clarke, to repair a complete rupture of the perineum, which occurred in the practice of a neighboring physician one week before. I found the levator ani and both sphincters torn, with liquid feces coming from the rectum, while pus flowed from the wound. The condition was such as seemed to render primary union impossible, but by means of washing, scraping refreshing and defining the ragged edges of the skin and mucous membrane and bringing the denuded surfaces into close apposition with buried sutures, the result was perfect with first intention throughout. The long delay after the accident, combined with the condition of the wound and the subsequent perfect result of the treatment, brought up a line of thought which I have since pursued with advantage in the primary repair of the injuries of parturition.

The immediate repair of the perineum has been laid down imperatively as the best procedure, and at present is the practice of competent physicians; in fact its neglect is considered almost criminal. But no one knows better than the operating surgeon and gynecologist the incompetency of the average obstetrician to make a satisfactory repair of the injuries peculiar to parturition, except where they are of minor degree. Their imperfect results are perhaps due to the indifference for careful technical work, often arising from a tendency to make light of an injury that they assume may cast a reflection on their ability as an obstetrician. The patient is rarely moved from her bed; the parts often only seen by bad light or not at all: disinfection is imperfectly carried out, and the work is faulty: that is. the edges of the skin may be brought carefully into apposition, but no attention whatever is paid to the mucous membrane, the various muscular structures, or the more deeply situated and perhaps most important injuries of the case.

In my opinion a primary repair of the parts requires greater skill and better surgical technique than a secondary operation. If the injuries are extensive, it is worse to do an imperfect operation than to leave the case alone, as it opens up the road for severe infection.

It is not common practice to make an inspection of the cervix until ready to discharge the patient, and primary repair of its injury, although it has been advocated and executed for several years by J. Price of Philadelphia, is not the usual custom.

If a deep cervical tear is not repaired it is a cause of infection, and a common means of subinvolution of the uterus with subsequent displacement and catarrhal inflammation.

With neglect of the cervix comes also an indifference for the treatment of deep vaginal tears, and in the majority of cases they are entirely overlooked.

Unless one is in the habit of examining the tears of parturition carefully, they can little realize their extent and the possible dangers they afford. The pelvic cellular tissue and the region of the broad ligaments are exposed to external infection in two direct ways, both of which are common. One is by a deep tear of the cervix passing beyond the cervicovaginal junction: the other is by a tear of the vagina which extends from a point in the roof or side and runs parallel with the urethra close to the neck of the bladder, to terminate internally near the cervix. These tears are often bilateral, with one side a little greater than the other. I have seen this particular vaginal tear so extensive that it reached the outside of the vagina, where it ended in the prepuce of the clitoris, thus running the full length of the vagina. If an inspection is not made in a proper manner this injury is entirely overlooked, and unless a careful repair is made the wound heals by secondary intention. This injury I believe is one of the most frequent causes of a form of pelvic inflammation represented clinically or by comparatively simple phenomena, but which becomes a source of great after-trouble owing to the adhesions about the ovaries and a tendency to anchor the uterus in an immovable manner and in an unnatural position. In a number of ovariotomies I have found the adhesions so great as to make the removal of the ovaries extremely difficult, yet there was absolutely no sign of tubal disease, and I have been at a loss to account for their development. In most of these cases there was a history of difficult labor and generally the use of forceps. After careful examination of many of these deep tears. through which I have passed my finger into the pelvic cellular tissue as far as the peritoneal covering. I feel that these tears offer the most rational explanation for the adhesion so common about the pelvic organs. The adhesions of the uterus in the vagina so frequently found during the repair of the cervix where the organ is placed high, can not be drawn down to the outlet but is firmly fixed to one side with a mass of hard scar tissue, are formed from the improper or neglected treatment of these tears. The form of puerperal septicemia which arises from these tears should be carefully distinguished and the fact recognized that the infection in the peritoneal space is direct and not by the way of or involving the uterus.

The perineal tears usually extend upward through the vaginal membrane that lines the lateral sulci, are rarely medial, owing to the thickness of the membrane in this region (the posterior vaginal column), and if the tear is bilateral, the corrugated membrane or raphe is raised in the form of a thick flap with the base *upward*. The tear along the lateral sulcus often reaches to a great depth. Emmet has described a tear where this posterior column is torn across in a deeper situation near the cervix and the lateral tears arising from within and extending outward, make a flap of the floor tissues with the base *downward* near the outlet. This flap curls up and heals in the form of a crumpled mass, which from its situation gives the appearance of a rectocele. I have seen but one example of this tear and believe it must be a rare accident.

Besides the tears in the vault already mentioned, are those which involve the bladder and urethra. They are very infrequent. The accidents of this sort, which in times past came from pressure necrosis, are now very rarely seen owing to the timely use of forceps. I believe that most of the cases of vesicovaginal and vesico-urethral fistulæ occurring at the present time are the results of forceps extraction of an occipito-posterior presenting head or breach, although my experience in these cases has been very limited. The perineum is usually well torn, and there is a median tear of the vagina above involving the deeper organs, which has a clean appearance as if cut by a blade of the forceps. The involuntary and constant flow of urine with every change in position very soon attracts the attention of the patient to the accident, and the physician is informed of it without any great delay.

The skin tear of the perineum is more or less straight, sharply defined and regular, extending in severe cases from the fourchette or hymenial ring to the mucous membrane of the rectum.

The rectal tears are rarely deep. Both sphincters are at times torn, and in all important lacerations the levator ani is injured. Frequently the sphincters are partly torn from their sheath and appear as a nipple-like projection half an inch in diameter and about an inch in length. There is a temptation to cut off this protrusion of muscle at the time of repair, but I think it unwise: it should be restored intact.

Beside the above tears, which I believe constitutes all that are of any magnitude, there are often innumerable smaller ones like a crack in the tissue, short and superficial, and rarely severe enough to require special attention.

From a practical experience with all the injuries of parturition above briefly described, I believe that I am justified in making the statement, that it is absolutely wrong for the obstetrician to attempt to repair the injuries of a severe labor, where the lacerations are extensive, without competent assistance and the proper means at hand as regards instruments, disinfection, etc.; or to do the work in an incomplete manner by simply sewing the muscles and outside skin together so as to give a fair temporary appearance exteriorly, which is foul within.

As I know from experience, that the parts can be satisfactorily treated within several days from the time of the accident, then the question of time is no excuse for indifferent treatment, nor the fact that the attending physician is worn out by an exhausting labor and perhaps very nervous about the issue. The fact that a primary repair will prevent a great many conditions which later require operative treatment, often of a capital magnitude, is sufficient reason why one should treat the case carefully from the beginning. The mere fact of a difficult labor condemns the patient to a period of lying-in, which is equivalent at least to the period of repair, and is a period which, in the lifetime of many women, is the most opportune for the treatment of her trouble. It is a positive fact that in many cases the period of convalescence would be greatly shortened by complete primary repair. In consideration of the above facts, I will propose the following deviations from the established custom, as giving a most satisfactory result immediately and as a preventive measure for many of the pelvic troubles of women.

When the injuries of a labor consists of more than a simple tear that does not involve the sphincters, the placenta and blood clots should be expressed from the uterus; a full dose of ergot administered; a pad rung out of bichlorid solution applied to the perineum; and then the patient should be given time for rest, unless it so happens that every measure for a repair of the parts has been previously arranged, competent assistance is at hand, and the patient is already under the influence of an anesthetic that was administered during her delivery. If it is a simple tear, a few stitches taken immediately is all that is necessary.

The duration of time that the surgical repair should be delayed will depend upon the different circumstances peculiar to each case. At least one hour should be given for the rest of the patient, and for the reason that by this time the full effect of the ergot will be realized, which may be of some use in counteracting any tendency of the anesthetic to relax the uterus. If the injuries have occurred at night, it will be better to wait until the next day, when there will be good light to work in, and if the obstetrician is incompetent to cope with the case, or his patient is far removed from help as in the country, it may be necessary to wait longer until the proper assistance is procured. I have been unable to discover any special advantage in the time of operating within the first ten hours after the injury. The retraction of the uterus is greater at the tenth hour than at the end of the first, but a little more care is requisite in refreshening the parts. The repair of the cervix is easier at the end of ten hours.

The preliminaries for the operation should be made in a careful manner; antiseptic solutions should be prepared for sterilizing the wound, the hands of the operator and his assistants, and an irrigator should be filled with the same; the instruments should be sterilized; a table covered with clean linen should be arranged where there is a good light for operating; a smaller table for instruments should be placed near it; a Kelly pad, or similar contrivance, with a pail for catching the irrigation, should be set in their proper places, and means for supporting the legs with the patient in a dorsal position should be at hand. For the repair of the multiple injuries of parturition I am in the habit of using animal sutures entirely, kangaroo tendon and fine catgut. This should be perfectly aseptic.

The etherized patient is placed upon the table so that the parts are exposed to good light and the legs are well supported. The hair about the parts is shaved off and the skin and vagina are carefully cleansed with soap and water, and finally with a solution of bichlorid. The rectum is dilated and also cleansed in a like manner. Clots of blood, which are usually present in the uterus, should be removed. The parts can now be satisfactorily examined and the exact nature of the injuries determined. The fingers are usually efficient retractors, but metallic ones can sometimes be substituted to advantage. With pressure of the hand of an assistant on the fundus of the uterus the cervix can be readily exposed and the tears, which are usually bilateral, extending toward the region of the broad ligament are easily recognized. They are repaired by closure with an over and over, or an interrupted suture, after scraping the raw surface with a sharp curette to insure union. The suture is exposed on the outside of the cervix but not in the canal, as it is passed just below the mucous membrane. With the closure of each stitch the blood should be carefully washed away with the irrigator and the corresponding parts adjusted with the help of dissecting forceps. In holding the cervix during repair I have found Pratt's rectal forceps of much help.

In closing the vaginal tears there is a simple rule to be carried out: viz., carefully bring together the torn edges of the mucous membrane and muscles that correspond to each other and unite them with sutures firmly and in close apposition, so that the raw surfaces are in contiguity and their exposure along the line of tear reduced to a minimum. This is the principle of the treatment in the case of a simple incised skin wound. The deep tears through the vault can be closed with an over and over stitch taken with a fine ligature, but all the remaining repairs can be easily manipulated and are best treated with buried sutures. If the repair is not immediate the raw surfaces should be scraped clean with the edge of a scalpel or sharp curette. A suture is taken in the tears of the mucous membrane that extend up the lateral sulci, beginning at the deepest point. There is no muscle to be united in this region as many suppose. If the tear is double then use one suture for each tear, which closes the vagina in the shape of a letter W. These sutures are not drawn tight until the other parts are united, because there would be less room for manipulation. The rectal tear is now closed in a similar manner, using very fine tendon and needle, the suture passing only through the muscular coat of the gut. The first suture is taken at the internal angle of the wound and should be placed sufficiently deep that no opening will be left which would admit a leakage of the contents of the bowel into the perineal wound. This line
of suturing is carried to a [illegible] just above the junc-
tion of the skin with the [illegible] membrane of the
rectum, and is fastened [illegible] is entirely discon-
nected from the other [illegible] g. By having
each line of sutures enti[illegible] te from the other,
should infection occur in [illegible] of one it will not
necessarily be transmitt[illegible] of another. The
deeper layers of the torn [illegible] oup of muscles and
the transverse perinei are [illegible] ught into apposi-
tion with a figure of 8 [illegible] the internal,
later the external sphinct [illegible] aired by [illegible]
suturing. As the value of [illegible] um dep[illegible]
the perfect condition of [illegible] les great
should be exercised to [illegible] edges
their normal position [illegible] a good
union. All of the [illegible]
placed, the ends of [illegible] the
mucous membrane [illegible]

seized and carefully drawn tight. Thus the wound is closed from infection by way of the vagina. If the ends of these sutures are brought out at the upper and outer angles of the tear, in the region of the caruncles then by tying the two ends together the closure of the wound, at the most dangerous point for gaping, is completed in a most thorough manner and at the same time the sutures are fastened. This applies of course to a bilateral tear. There is nothing now left to be done but an apposition of the remaining outer torn portion of the levator ani and transverse perinei and the union of the skin wound, which is easily performed with two or more layers of buried sutures.

If there has been a tear in the neck of the bladder or urethra, the opening in the mucous membrane of these organs should be closed with a fine buried suture of kangaroo tendon passed by the help of a sound in the urethra and bladder, and with great care that no part of the suture extends out upon the mucous surface. The loose submembranous connective tissue can be gathered up with a line of sutures over the first layer to reinforce the wound from leakage. The vaginal tear is now closed in the manner already described. The repair of the bladder and urethra should be done immediately after that of the cervix while there is yet plenty of room to work in.

After the injuries are all repaired the urine is drawn, parts irrigated and a protective suture is passed just above the lower angle of the vaginal introitus through the labia of either side. The two ends of the suture are tied together, bringing the surfaces of both labia into close juxtaposition above the seat of injury. By thus pinching the two lips together the top of the perineal wound is greatly protected from the secretions in the vagina, which can not flow over the line of repair, but must rise higher to pass over the protective suture; and in case the nurse is obliged to catheterize, should she depress the inserted instrument, it would be prevented by the double strand of the ligature from bearing down upon and prying open the top of the perineal wound, one of the weakest oints in the repair. This suture can be removed in wo or three days and has nothing to do directly with the closure of the perineal injury. In bladder and urethral injuries a catheter should be passed and fastened *in situ*. It is kept here for three or four days.

Results.—If the case is done in a skilful manner, healing will occur by first intention throughout and there will be no constitutional disturbance of the patient except a slight fever of reaction, which is rarely greater than 100 degrees F. It may be criticised that a technical error would lead to a severe infection with great sloughing and danger where so much buried material is used. I must say that the worse sloughing of the perineum that I have ever seen was in the practice of a physician who closed the wound with external sutures, the infection coming by way of the vagina. In my own experience I have had but one complete failure and, recognizing it was inevitable by the fourth day, I again etherized the patient, opened up the wound, cleansed it thoroughly and reunited the parts as before. The case healed after the second operation with primary union. In a number of cases where the work was performed under trying conditions, a small abscess formed in the center of the perineum. This forced an opening and discharged spontaneously, sometimes into the vagina, and at other times through the skin. These cases have all healed kindly leaving a satisfactory perineum without complications, but the convalescence was slower. The technique must have been faulty in these cases. My worst cases, including vesical and urethral fistulæ, have all healed by primary union, probably because the greatest care was taken to obtain an aseptic operation. I have never had a failure in the union of the sphincters.

In my earlier operations on the cervix I practiced the introduction of some foreign body into the uterus for the purpose of draining that organ and in cases of secondary repair where there was extensive removal of tissue to help establish a patent canal. I found the custom an evil one in cases where there was simultaneous repair of a complete perineal location. The cervix in its natural position rests against and is supporting the rectal wall of the vagina, usually an inch and a half to two inches above the introitus. The pressure is received upon the posterior column or raphe, which from peculiar construction is well fitted for the purpose. When the parts are repaired the cavity of the vagina is closely occupied, and any foreign body tends to disturb the natural relation, which in a case of uterine drain produces pressure upon the lateral sulci, where the mucous membrane is very weak and the partition between the lumens of the vagina and rectum thin. In deep tears, a foreign body in the vagina will tend to open the internal ends of the wounds of the rectum and vagina behind the sphincters, making a vaginorectal fistula. This has twice occurred in my practice. In these cases I removed the drain early, as soon as I discovered the accident, kept the vagina clear by douches, and the fistula closed spontaneously. Since giving up this mode of draining I have had no further trouble.

Conclusions. In my opinion, the obstetrician who today boasts that in his practice he has no lacerations of the cervix or perineum, proclaims to the world his ignorance of this branch of his profession. It is as much the duty of the obstetrician to his patient to see that she is properly repaired, as to see her safely delivered. The public should be educated to the fact that injuries to the soft parts of the parturient canal are often inevitable, and that such injuries only cast a reflection on her professional attendant when their after-treatment is neglected. The physician in whose practice a severe laceration of the parturient canal has occurred, can protect himself in no better way from a legal attack on alleged malpractice, than by calling in assistants, who serve as witnesses, within twenty-four hours of the time of the accident, and repairing properly, or offering to, the injuries which his patient has sustained. There is no better time to repair the injuries of parturition than within twenty-four hours of the time of their occurrence; such immediate repair of the injuries will often hasten convalescence and prevent in many cases, severe pelvic complications. The obstetrician should be educated to do this part of his work in a more careful and thorough manner. The injuries already sustained by a multipara in previous labors should be an incentive, rather than an objection, for the careful treatment of the lacerations of her present delivery, because a repair of her total injuries can be accomplished at the same time.

An early symptom of carcinoma of the esophagus is afforded by decreased flexibility of one of the vocal cords. An instructive instance is related in the *Deutsche Med. Wochenschrift* of November 4.

REMARKS ON THE RELATION OF THE UTERUS TO DESCENT OF THE PELVIC FLOOR, AND TO GENITAL PROLAPSE.

Presented to the Section on Obstetrics and Diseases of Women at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY GEO. ERETY SHOEMAKER, M.D.
GYNECOLOGIST TO METHODIST HOSPITAL.
PHILADELPHIA.

As the title implies, it is not intended here to formally cover the field of genital prolapse but to remark upon one phase of it, and to emphasize the fact that the uterus is not the sole offender, but that, in greater or less degree, all the other pelvic organs and tissues are involved to such an extent in some cases that even after the uterus is completely restored to its position, the prolapse of vagina, rectum, bladder and tissues of the pelvic floor continues.

There seems to be, in the minds of some, an idea that the uterus descends alone through a normal tube, the vagina, because of some relaxation of suspending supports above. This idea leads to attempts to cure prolapse by shortening round ligaments alone, by fixation (literal) of the uterus alone to the abdominal wall, or even to the performance of hysterectomy followed by fastening the cervical stump to higher pelvic tissues, while the relaxation, sliding and stretching which have occurred in the pelvic diaphragm are left untreated. Ultimate failure to cure must be the result of this policy. The truth is that in varying degree in different cases, the uterine prolapse is only a part of a vast hernia through the inferior pelvic strait of the pelvis; that in this hernia are involved bladder, rectum, peritoneal pouches in front and behind the uterus, with or without bowel contents; also the muscles and fasciæ of the pelvic floor. All of these structures do not descend to equal degree, but there is a gradual sliding in different planes. The uterus is often forced furthest down by intra-abdominal pressure and gravity, the posterior bladder wall less so, the anterior bladder wall still less so, and so on with each succeeding plane of connective tissue until the bony pelvis is reached. By thrusting up the uterus, this whole prolapsed mass may be made to telescope back, partly into position, but not wholly. No operation can be permanently successful which aims to deal with the uterus alone and does not take into account the sliding planes of stretched tissue and the telescoping movements when the cervix is thrust up or down.

This is best illustrated by the following case, which shows that the uterus may be even higher than its normal place in the pelvis and yet the bladder and much of the vagina be outside the vulva.

Mrs. X., a young and healthy multipara, was referred to me for operation by her physician because her "womb came out," giving rise to chafing and various discomforts. He had made no careful examination, but saw simply a large pinkish mass, the size of the fist, protruding from the vulva, and sent her to me without further investigation. Upon examination I found, indeed, a large genital prolapse outside the vulva, larger than the fist, but it was made up of anterior vaginal wall and bladder in front, and rectocele behind. The uterus so far from being an element in the case was, to the surprise of patient and physician, found to be pregnant six months. It was within the abdominal cavity, having risen normally above the superior strait. The cervix was normal in size and high up. Here was a case in which Nature by pregnancy had restored the uterus temporarily to its normal position in the body without dragging up enough of the other elements of the genital hernia to attract the patient's attention. In fact, the prolapse continued. A hundred diagrams or theories could not better demonstrate the position that any effort to cure this woman by any operation for suspending or removing the uterus would be futile unless something were also done to the pelvic floor. The case aborted shortly afterward and is now awaiting operation. What shall this be? First a serious attempt from below to restore. not the perineum but the integrity of the pelvic floor, of the whole pelvic diaphragm. By operating within the vagina, to endeavor to reach with stitches and take up the higher and deeper planes of pelvic fascia and muscle. When the uterus is large and the cervix long or hypertrophied, amputation of the cervix from below is a great help as it is preceded by dissecting off the vagina from the cervix, while the method of sewing shortens materially the vagina and implants it higher upon the uterus, virtually at the same time taking a reef in utero-sacral attachments. In addition I believe that uterine suspesion should usually be done, or in very rare cases of enlarged uterus, hysterectomy, but the main effort must be concentrated upon the vagina.

It is of interest, in passing, to note the curious tolerance of this patient to septic influences, no doubt owing to long protrusion of the uterus from the body. She aborted, as has been said, at six months. Her physician found, a few days later, to his horror, that finding herself unable to pass her urine owing to protrusion of the bladder she would take her hands and push everything within the vulva, when the husband with unwashed hands would catheterize her with an instrument which he had bought for that purpose. No harm resulted!

THE INFLUENCE OF OUR SCHOOL SYSTEM ON THE HEALTH AND DEVELOPMENT OF THE CHILD.

Presented to the Section on Diseases of Children, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY E. STUVER, M.Sc., M.D., Ph.D.
Member Colorado State Medical Society (Vice-president 1894),
American Medical Association, International Medical
Congress (Berlin); Active Member National
Educational Association.
RAWLINS, WYO.

(*Concluded from page 1252.*)

Answers to No. 6.—To most persons it may seem that such a question as this is entirely superfluous; that the dictates of humanity and common sense would make such a practice an impossibility. From my personal experience as a member of a school board and as a practicing physician however, I am sorry to say that the practice is more prevalent than I would have believed it to be without a thorough investigation of the subject. Indeed, I am satisfied that even superintendents and principals of schools do not fully appreciate how frequently teachers err in this matter. This can probably be explained, in part at least, by the fact that it is a delicate subject, about which parents do not like to make complaint, and which does not receive the attention and discussion in teachers' meetings that its importance demands. Whatever may be the cause of the practice it certainly exists to a

serves to implant in him doubts as to the teacher's ability to instruct him aright. *b.* Constipation, headache, eye strain, and in girls anemia, neurasthenia, chlorosis, cystitis and, in some cases, perversions of the sexual system as in amenorrhea, dysmenorrhea and their sequelæ.

Prof. Leonard Freeman, B.S., M.D., of Denver: I do not know. It should not exist at all unless real deception be exposed. *a.* May lead to masturbation through irritation of the neck of the bladder by accumulated urine. *b.* Irritation of the prostatic urethra with coincident nervous phenomena.

Pres. Alfred Holbrook of Lebanon, Ohio: I do not know that any teacher is so unreasonable anywhere. Hourly recesses make restraints unnecessary. *a.* Being entirely unreasonable, it makes all restrictions seem unreasonable and unjust.

Elizabeth K. Matthews of Des Moines, Iowa: Am sorry to say it, but it exists to a very great extent.

Prof. J. A. Larrabee, M.D., of Louisville, Ky.: Does not exist to any extent in our schools. Personal and private hygiene concerns the home training and teachers so instruct our pupils. *a.* Neglect of personal hygiene, either in the schoolroom or at home, is equally deleterious to the moral status of the child. When necessity demands, a modest signal should be given. *b.* The physical effect of delayed defecation or urination concerns all the functions of the body and results in imperfect cerebration, hemorrhoids and, in females, in retroversion of the uterus and chronic indigestion in both sexes.

Answers to No. 7.—This is a very important question and one about which there is a great diversity of opinion. There can be no doubt but that if children could have plenty of outdoor exercise in pure air, surrounded by moral safeguards, and the time now devoted to entertainments, parties and other social dissipations were largely spent in sleep or devoted to healthful recreation or a judiciously selected course of general reading, children would enjoy better health and be better off in every way.

Whether home study will be beneficial or hurtful to a child depends much on the surrounding conditions and the motives or incentives which prompt it. If done through enthusiasm or a love of truth for truth's sake, the results will likely be beneficial; if, on the other hand, the child is impelled to study by the slave-driver's lash or threats of failure and disgrace, the effects will in all probability be injurious. Unfortunately, under [illegible] high pressure methods of education, [illegible] examinations and grand stand plays for public show and approval, truth is lost sight of and children are spurred on and incited to cram, memorize and fill themselves up for examinations and public exhibitions regardless of the permanent effects of such a course. This sort of work keeps the child in a constant state of excitement, worry and anxiety; the brain is irritated, the vitality lowered, the mind weakened and the importance of truth and honesty lost sight of. Under such a system even the brightest and best pupils will lie awake nights and worry over their grades, their examinations and their promotions, when never a thought or care on such matters should disturb them. Nor is this confined to the higher grades of the schools but also applies to many pupils in the primary grades.

The period of puberty is one of rapid development and growth and makes great demands on the strength and vitality of the child, who as a consequence should be very carefully protected against undue excitement or anything that will divert the vital forces from the great work which they have to perform.

Dr. Miller (*vide Cincinnati Lancet-Clinic*, Feb. 6, 1897, p. 159), very clearly depicts the condition of the child as follows: "The child fatigues much more readily, that is, his organism is much more quickly depleted and poisoned during the periods of most rapid growth. The average boy has the most rapid growth between the ages of 14 and 16. In these two years he increases in weight by as much as he did during the entire six years preceding the age of 14. At this period of most rapid growth, the period of pubescence, the brain loses considerable weight because of the fact that the usual blood supply is lessened by a portion being withdrawn to nourish the viscera and other organs undergoing revolutional changes during this period. While the weight of the brain is only one forty-fifth of that of the whole body, it requires one-eighth of all the blood to nourish it. At no time in his whole school career is the boy so deserving of sympathy as at the time of most rapid growth. In all learning, two great features are involved; proper presentation of material by the teacher and proper attitude of mind on the part of the pupil. Seldom, if ever, can the latter condition be supplied by the boy or girl in the midst of the physical and mental revolutions and evolutions of pubescence. The great curse of the age is the demand for rapid education. Parents and teachers crowd the children through a long year's work. Health is sacrificed for promotion. What is learned while the child is fatigued is soon lost, the mind's force being equally dissipated. Vital force is required faster than it is generated. The work of today is done on tomorrow's credit and the system of a child is wholly at a loss to protect itself against disease and accident."

Reuben Peterson, M.D., of Grand Rapids, Mich. (*vide* JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, Dec. 19, 1896, p. 1269) writes as follows: "The growing girl who should spend most of the time in the open air with never a care in the world, is closely confined in a schoolroom the air of which is so vitiated as to be scarcely capable of supporting life. Here she may be found, ambitious to excel in her studies, poring over her books with back bowed and chest contracted. If the remainder of her time were spent in recreation the evil effects of overcrowded schoolrooms might be counteracted, but such is not the case. The parents are, ambitious that their daughter shall take high rank in her studies, and that accomplishments such as music and painting be acquired at an early age. Hence the girl is urged to still greater mental efforts. Thus the nervous force so needful at puberty for the establishment of the menstrual function is wasted in the acquisition of what may be considered trifles compared with perfect health. He (the family physician) should demand that the hours of recreation in the open air should be lengthened and the school duties be lightened."

Fifty-three educators and thirty-four physicians answered this question more or less fully. While there is a wide divergence of opinion from absolute condemnation to warm approval of the practice, still all insist that the work should be carefully guarded and not carried to extremes and that the health should be properly cared for at the same time. When these conditions are fulfilled and the pernicious habit of attending parties, keeping late hours and indulging in

much in his efforts at bread winning, for, in my opinion, the father should be a mother just as far as conditions will allow. I feel that the doctor should impress the father with that fact, for the doctor is placed in a position to be of more service to the parents than anyone else. The clergyman is not in it for one minute compared with the doctor. We as physicians should explain to the parents that they should talk with their child as to its duties to the teacher. The child comes home with its little tale of woe, and too often the mother listens to it sympathetically and does not realize the duty they bear to the teacher. I have been in the habit of instructing the children that they owe a debt to the teachers and I tell them that I must hear from the teacher that they are good children, and they must learn to love their teacher. If the child comes home with a criticism of the teacher he should be corrected at once. He should be taught to respect as well as love his teacher, and that it is his duty to make a friend of his teacher and that if he can not make a friend of his teacher he is to blame. If the child is taught in this way he will have a good time in his school, he will love his school and love his teacher. The parent having done his duty in the question of co-operating with the teacher, then if there is anything wrong he may investigate the teacher.

Dr. S. E. Woody of Louisville—I have only one criticism on the subject. Everybody is jumping on the school boards and school teachers, but it seems to me we should be thankful for what we have. When I think of the wonderful advance made since I sat in the schoolhouse, with vitiated air except when it was relieved by numerous drafts, sat there from early morning until dewy eve, sat there bound down by a stupidity that was inimical to all advance—contrast that to the great variety of study and the beautiful surroundings children now have. I think instead of jumping on these men we should thank those who are making teaching an art instead of what it was a few years ago, a trial of main strength and awkwardness.

Dr. Jeffries of Chester—The Doctor is looking back and calling our attention to the deplorable condition of the schoolhouse when he was a schoolboy. I am sorry he did not compare the average young man then. I would call the attention of the audience to the average young man today as, after the receipt of his diploma, he goes seeking for health and after seeking from the East to the West he comes back on the check forwarded from the East to bring him home.

Prof. J. Henry Bartlett of Philadelphia—No more serious indictment could be brought against our school system than that it interferes with the health and development of the child. Fortunately, we live in an age when an intelligent co-operation of forces makes the reverse of this charge true, and our schools may be, in fact as well as in theory, what Dr. Stanley Hall calls them, palaces of health. Even a false regimen of hours and diet in the homes is measurably overcome by the regularity of the school life; if combined with this regularity there is a measure of preventive and corrective physical environment. Educators owe much to the medical profession for pointing out lines for the hygienic treatment of the child in schools. I am here today to submit some evidence of practical experience in these lines in one of the schools of the city. It were impossible, however briefly, to touch all the lines that aid, directly or indirectly, in efforts for the health and development of the children. The medical profession has indicated many lines of work and most of these today are bearing fruit. My remarks are confined to two subjects, but the progress in them is measurably typical of all. City conditions at home and school reflect the tension of business life and the tendency of the age to extreme specialization, so that very great effort is needed to prevent a one-sided development. Business arrangements for instance control the habits of our people (in too many instances including the children) in the important matter of the midday meal. Many of our larger financial and even mercantile institutions recognize the effect of this circumstance. and as a measure of economy in securing working ability provide their employes with a dinner. Ideal conditions for children would include a substantial luncheon with the family circle near the noon hour, but in a large percentage of cases this is quite impracticable, and it remains for the school as a matter of self-protection, if for no better reason, to invade the domain of domestic economy and add a kitchen and dining-room to its equipment. In varying degrees this necessity is recognized. In Boston all the high schools have arrangements for luncheon; in Brookline there are ample accommodations in the magnificent high school building, and in Philadelphia a considerable variety of arrangements, from the basket of pretzels at the school gateway to the attractive dining-room of a modern restaurant, may be seen. Speaking for the latter, I may be permitted to remind you that even in matters of this kind the law of development is operative. Parents and children, as physicians well know, need to be educated as to when to eat and what to eat. The stage of sweet buns and fancy cakes precedes the stage of cocoa, milk and nutritious soups. At no distant future our more progressive schools will have *all* children sit down at midday to an inviting repast. Let us be encouraged that the matter is growing and let our medical men believe that their labors in this direction are bearing fruit. On the direct efforts for physical development in our schools, volumes have been written and the gymnasium is amply justified as a necessary adjunct of a good school. It would be out of place for me to deal with this question in its larger bearings. I can but submit to you in a form of a report a very brief chapter of results from a school gymnasium for the last year.

The particular record to which I call your attention deals with 108 girls of 12 years and upward. Seventeen of these at the year were distinctly abnormal in their development, and these have all been "materially helped in *all* parts"; 68 of the 108 have gained in chest expansion, 58 in flexibility of the waist and abdominal muscles, 41 in depth of chest, 50 in increased breadth of shoulders, 74 gained in lung capacity, 56 in strength of back. Of the 108, 67 had shoulders and hips uneven in the autumn; 33 of these were made even and 34 were improved. Eleven of the 108 had spines distinctly curved; 5 of these were made straight and 6 much improved. These figures have reference to school gymnastics taken in two half-hour periods each week, but they reflect also the effect of a pretty faithful effort to overcome defects by free movements prescribed for home work. This is more apparent from the fact that 10 of the total 108 have losses of development recorded and these 10 are those who have not been interested in carrying out the prescriptions or fulfilling the conditions of the class work as regards dress and other circumstances.

I have said enough and reported enough to indicate how our school system can meet the exactions of hard conditions and make an environment in which development shall not be retarded nor health sacrificed. It is not a simple problem, it involves many elements and study and labor along many lines.

I adopt the words of a recent résumé of the results of child-study in one of our educational journals, as a further acknowledgement of the service of the medical profession to education as well as to indicate how far-reaching the efforts are to correct the *defects* of our school system: "The physician is becoming interested in the schools, as at one time was the clergyman. As the physical basis, or at any rate the physiologic concomitants, of intellectual deficiencies and moral defectiveness are coming to be more clearly understood, the physician's function as an instructor of teachers and as an examiner of children as to sight, hearing, touch and symptoms of fatigue or illness, as to temperamental characteristics and 'nervous' peculiarities, as to differentialites in age and sex, are being in turn more fully apprehended. School hygiene, not only as related to problems of heating, lighting, ventilating and sewage, but also to the manner of seating, length of sessions, frequency of recess, size of playgrounds, modes of recreation, as well as to individual 'health,' nourishment, cleanliness and raiment, and finally a more rational instruction of the children themselves in the structure and functions of their bodies, their use and abuse, not to mention the application of gymnastics, all these matters have come to be of vital concern jointly to mothers, teachers and doctors."

SURGERY ONE HUNDRED YEARS AGO.

AN HISTORICAL STUDY

BY DR. GEORGE FISCHER.

DEDICATED TO THE GERMAN SURGICAL ASSOCIATION.

TRANSLATED FOR THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION

BY CARL H. VON KLEIN, A.M., M.D.

(*Continued from page 1266.*)

XIX.—DISEASES OF THE URINARY AND GENITAL ORGANS AND OF THE RECTUM.

Lithotomy; Catheterism; Ischuria (strictures, swelling of the prostate); Cystotomy; Hematuria; Nephro-lithotomy, extirpation of the kidney; Hydrocele; Sarcocele; Castration; Varicocele, testicles in the groin; Phimosis; Amputation of the penis; Symphyseotomy; Vesico-vaginal fistula; Atresia of the vagina; Dropsy of the ovaries; Fistula ani; Hemorrhoids; Atresia and strictures of the rectum.

"There are few operations to which surgeons have turned so much attention and which they have performed in so many ways and with so many kinds of instruments as *lithotomy*. . . . The operation deserves the preference over internal remedies; it relieves certainly and quickly. In recent times it has been so perfected that one can be almost certain of a fortunate result if it is performed in time by a practiced hand and with a certain precaution." Thus wrote Richter. Lithotomy united the surgeons of all nations in the effort to wrest this operation from the hands of the itinerant lithotomists, with their unsavory secret traffic, and to restore it to science. They distinguished four methods, the major and minor apparatus, the suprapubic and the lateral lithotomy. In order to better locate the various modifications of the operation let us group them according to the direction of the internal incision, as urethra incision, prostate incision and bladder incision.

The urethra incision, or the method of the major apparatus, was originated by Giovanni de Romanis (1525) and made known by his pupil, Mariano Santo (Mariano lithotomy). By this method only the urethra was opened and further enlarged. A grooved bent probe was inserted in the bladder, and in the middle of the perineum between the scrotum and the anus everything up to the bulbus was separated, then by means of a dilator the urethra was enlarged and the stone extracted with tweezers. If the stone was of any considerable size the urethra and prostate were so bruised and lacerated by these manipulations that urethral infiltration was unavoidable. Almost half of the patients operated on died. This method, the traditional secret of the Colot family since 1556, was made public (1727) by the last of the family, Franz Colot, and was brought into prominent use be the lithotomists of Norcia. Maréchal and le Dran perfected it, the latter especially improved the bandage after the operation. Schmucker also operated according to his directions, but with a somewhat larger incision, from fear of laceration, and out of twelve lithotomies which he performed during his lifetime, he lost only one. He never needed more than two or three minutes and "could almost maintain that not a single patient need die in this operation if the operator performed it with sufficient skill." The method of the major apparatus, however, was soon displaced from lithotomy and at the end of the century was almost entirely discarded. Morand had reckoned that out of 812 lithotomies performed in Paris within eight years with the major apparatus, 255 proved fatal.

The prostate incision, by which only that gland was cut through and the bladder not injured at all, or only at the neck, is classed with the lateral incision. Franco had originated it in the middle of the sixteenth century. He introduced a grooved probe into the bladder and had it pressed obliquely backward by an assistant in order to force the urethra somewhat to the left. Then he made an oblique incision which began two centimeters in front of the anus and ended in the middle of a line from the anus to the tuber ischii. The urethra was slit up the probe, along whose groove the knife was pushed obliquely through the prostate to the neck of the bladder. The lithotomist, Frère Jacques, first brought the lateral incision into practice. Rau received the operation from his hand and Heister learned it from Rau (see chapter ii). Heister recommended Rau's modification, while Camper rejected it, because not only the body of the bladder but also the neck and the prostate and urethra were affected; it was also dangerous an account of a possible injury to the rectum and to the seminal vesicles. The operation received a further improvement from Cheselden, who really first led the educated surgeons to accept the lateral incision. The number of unfortunate results which he had at first and acknowledged (three times he performed a lithotomy and found no stone) drove him unceasingly to improve his method. In the first, where the incision fell behind the prostate into the body of the bladder, frequent urine infiltration ensued; in the second the urethra was cut behind the bulbus and the prostate was cut straight through to the bladder; in the third, which he retained as the best, a grooved lithotomy probe was introduced into the bladder and adjusted with the groove toward the left side of the perineum. Then, left of the raphe an incision was made which began behind the scrotum, ran obliquely downward and ended in the middle of the anus opposite, a half an inch from its edge. The left forefinger inserted in the wound pressed the rectum back and guided the small, slightly convex and pointed knife attached to the groove of the probe. Directed upward and forward, it cut the urethra together with the prostate, whereupon the tweezers were introduced on a broad gorget. The fortunate results of which Cheselden boasted from that time on (six fatalities among eighty operations) were the reasons for Morand being sent to London (1729) to learn this method and introduce it into France. He himself, in the following year, had seven successes out of eight lithotomies, and later six fatalities out of eighteen operations. In the Paris Charité in five years (1731–1735) seventy-one cases were operated upon according to Cheselden's method with thirty-one deaths: in the Hôtel Dieu within eight years, 604 cases with 164 deaths. Sharp and Bromfield, who devised some four-bladed tweezers, la Faye and Bertrandi, all recommended Cheselden's incision; in Germany Senff and Henckel especially advocated it, so that in the middle of the eighteenth century this method displaced all others.

They endeavored to lessen the difficulty of it by the invention of a host of new instruments. Richter's criticism in this connection says: "The least which one can say of most of them is that they are useless and superfluous, since one can, at all events, make this little incision with any long narrow scalpel." The lithotome caché of Frère Cosmo raised the greatest renown. This knife, four inches long, narrow and somewhat curved, was covered by a sheath attached in front, and could be released by means of a spring. Attached to a grooved probe and inserted, they touched the spring and in this way cut through the neck of the bladder. For very large stones Frère Cosme used tweezers provided with iron teeth, with which he thought he could break the stone. Among the advocates of Cosmo's method were Acrel (five deaths in twenty-two lithotomies), Steidele and Richter, who described it as the model of lateral incisions.

After it was made known through dissections that by this method, received so favorably in France, the rectum might be injured and the bladder pierced entirely through, it found many opponents. Frère Cosme defended it and declared that of seventy-eight patients upon whom he had operated with his instruments only six had died. In general, Le Cat, and with him the whole academy, opposed the lithotome caché. As a pupil of Morand, Le Cat had at first employed Cheselden's method, but discarded it after 1742. While the Englishman advocated slitting the prostate to a considerable length, Le Cat announced the principle of cutting through the gland to a less extent, rather risking its laceration in case of large stones and of making the external incision much larger than the internal. Le Cat went to Paris and operated publicly before the Académie de Chirurgie with great success; while once for a period of six years, and among thirty-eight operations, he did not lose one patient. Later he had six fatalities out of nine cases in a single year. At the time of his death (1768) he had performed 310 lithotomies. Günz, Pajola and C. C. von Siebold in particular, brought Le Cat's method into use in Germany. C. C. von Siebold once performed a lithotomy twice upon the same patient in one year, and with success. On the contrary, Richter, whom one of his critics reproached with a lack of observations, since he, with the rarity of cases of stone in Göttingen, had never operated or at most very seldom performed the operation, advocated the principle of Frère Cosme, namely, to always fit the incision as far as possible to the size of the stone so that it could be extracted without force instead of making a small incision, according to Le Cat, and giving it the proper size by extension. To him the danger of a long hemorrhage did not seem so great as that of a forcible extension of the wound. On the other hand, Pouteau adhered rather to the principle of Le Cat. Pouteau ascribed his fortunate results to the fact of gradually extending the wound, in which of 120 patients only 3 died in consequence of the operation. For the incision in the perineum Richter recommended the urethrotome of Le Cat; for the incision in the prostate and the neck of the bladder,.the lithotome caché. Besides the latter, as really a perfection of Cheselden's method, a new instrument was devised, which was said to guard against the danger of a possible slipping of the point of the knife; it was the cutting gorget of Hawkins, a surgeon in George's Hospital in London (1753). It protected the rectum and served to introduce the lithotomy tweezers. The gorget raised great applause and displaced, especially in England, the lithotome; Bell and Cline modified it. Desault, who first employed it in France, gave the cavity a stronger surface and shortened the blade; however, he preferred to operate with the lithotome. His results were very varied; once in the Charité fourteen of his patients who had been operated upon died one after another, while twelve others who were operated upon at the same time by one of the monks all recovered; on the contrary, he had in the Hôtel Dieu only two deaths from twenty-two lithotomies. To remove the stone only after a few days after the operation, had already been advocated by P. Franco, and it now found defenders in Maret and Louis. The latter attributed the unfortunate result of the operation chiefly to the fact that it had been completed immediately and he asserted that he had not lost a single patient. Camper, Richter and Loder also favored this method.

We have hitherto had in mind only the usual method of the prostate incision (sectio lateralis); there was besides an incision on the median line and one on both sides. For the former, Vacca Berlinghieri devised the method of making the incision on the median line, behind the bulbus urethræ, to the pars membran.; then a knife was forced into the neck of the bladder and the prostate slit exactly in the middle. But in this way the rectum and seminal vesicles were exposed to injury. In regard to the sectio bilateralis, le Dran recommended the division of the prostate on both sides, but Dupuytren first developed the method further and introduced it into practice.

By the third main course, the bladder incision, the body of the bladder was opened directly by various methods. Celsus had already briefly described an operation from the perineum outward, which later received the name "minor apparatus," or Guy de Chauliac's method, because this surgeon recommended it anew and apparently was the only one in his time who practiced lithotomy. According to Celsus the operation should only be performed in the spring and and in case of boys between 9 and 14 years of age, because only with them could the stone be felt through the rectum. For the extraction nothing further was necessary than a scalpel and perhaps a pair of dressing forceps. An assistant took the child upon the lap so that he sat almost vertical; another held the strongly flexed legs as far apart as possible, and at the same time fastened the open hands at the knuckles. The operator inserted two fingers of the left hand high up in the rectum while an assistant pressed the stone against the perineum with the hand laid above the pubis. The operator endeavored to seize it with his fingers, pressed it to the left and forward, and cut it out. If the stone did not come out of the wound of itself it was extracted with the fingers or with a spoon. In the treatment according to Celsus, Heister first showed how disadvantageous it was to be willing to operate only in the spring, a rule which was pretty generally followed; although the method was confined almost exclusively to the charlatans, yet he advocated it in case of children and for small stones. In adults it was only permitted if the stone was wedged solidly into the neck of the bladder or the pars membr. and it was contra-indicated in case of angular stones and for large strong persons. As an injury to the rectum or the seminal vesicles was easily possible, this method was almost entirely discarded by the end of the century. A second operation from the perineum was that of Frère Jacques previously mentioned; a third, that by Foubert of Paris (1727). He would thrust a grooved trocar between the urinary passage and the neck of the bladder into the previously filled bladder, allow a part of the urine to run out through the groove and then insert a long knife into the bladder. This method produced no good results. It was too difficult to find the right place for the trocar puncture and the bladder with certainty, and a swollen prostate might be injured.

In spite of all the improvements of the lateral lithotomy, it was impossible to remove very large stones without causing various injuries (P. Camper), insomuch that attention was attracted anew to the suprapubic method. P. Franco, the originator of it (1561), operated upon a 2-year-old boy in Lausanne, according to the method of Celsus, although he would not remove the stone. But from the rectum he would lift the stone (as large as a hen's egg) so high with his fingers that he could distinctly feel it near the linea alba, above the pubes; he thereupon made an incision and extracted it. Although the child recovered, yet Franco cautioned against a repetition of this operation on account of the possibility of an effusion of urine into the abdominal cavity. Although Rousset set forth the advantages of this method, defined it in a rational manner and laid the greatest stress upon previous filling of the bladder (1590), yet the suprapubic lithotomy only came into favor in the eighteenth century. Indeed the contest with the lateral incision continued, but the supapubic was generally recommended for large stones, while for callous bladder and in case of children and fleshy persons it was disapproved of. Douglas and Cheselden in England, Morand, Winslow, le Blanc and Frère Cosme in France, Boretius and Heister in Germany, interested themselves in the matter. Douglas, of the Westminster Hospital in London first performed the operation anew; he syringed the bladder with barley water, made an incision along the linea alba, opened the bladder with a curved scalpel and removed the stone with the fingers. Cheselden and Morand, who first performed the sectio alta (1727) in France, operated in a similar manner. There came to the knowledge of the two Englishmen and two other surgeons, within a few years, thirty-one suprapubic incisions with only five fatalities. In Germany, Pröbisch, regimental surgeon at Königsberg, first accomplished the operation (1726); Senff of the Berlin Charité followed him in 1728. Frère Cosme devised a special modification of the operation (1779) in that he, in the suprapubic lithotomy, bandaged the urethral incision from the perineum in order to conduct the urine and pus off freely, to which he ascribed the entire success of the operation. Without previously expanding the bladder by injections, he severed the pars membr. as in the sectio lateralis, as far as to the prostate. He then cut through the soft parts over the pubis to the linea alba, and perforated this with a so-called trocar-bistoury. Through the opening of the urethra into the perineum a somewhat curved silver tube, in which a pointed needle lay, was introduced into the bladder, which was raised by the mouth of the tube and the needle thrust through. The peritoneum and intestines were held back by the hand. bistoury fixed in the groove of the needle enlarged e bladder, whereupon the stone was removed with he fingers, which Morand had already extolled as a great advantage over extraction by means of tweezers. Frère Cosme reported eighty-two operations, for the most part successful, and he found many supporters until Ev. Home and Loder entirely discarded the simultaneous incision of the perineum. In the suprapubic lithotomy the surgeons especially feared the entrance of urine into the abdominal cavity. To avoid this Frère Cosme applied an elastic catheter from the perineum outward; Deschamps made the puncture of the bladder through the rectum and Richter adjusted a small bandage to the wound in the bladder. They were also apprehensive of injuries to the peritoneum. To guard against this the bladder was previously distended by means of injections, although Morand protested against such a procedure. Richter at first thought that in opening the empty bladder a particular difficulty of the suprapubic lithotomy was removed, but in later years he laid great stress upon filling the bladder and advised an injection of about a pound or a pound and a half of lukewarm water. B. Bell, on the contrary, preferred that the patient should retain the urine, since the sudden distension of the bladder by injections is painful and dangerous. Heister pressed the peritoneum, with the finger, backward and downward from the symphysis. After the operation he applied adhesive plaster, while B. Bell joined the upper part of the abdominal wound by means of a twisted suture.

The opening of the bladder through the vagina was indeed successfully accomplished a few times (Gooch), but it was not general because of the persistence of the fistulæ, etc. C. L. Hoffmann of Münster suggested the rectovesical incision (1779) after he had twice seen a bladder stone removed through an abscess induced in the rectum; this first gained credit through Sanson (1815). Lithotrity as a method of operation did not yet exist.

Condensed in a few words, the judgment of the surgeons in the second half of the century agreed that the lateral lithotomy should always have the preference, with the single exception of cases in which the stone was very large; then the suprapubic incision was necessary. If in a lateral incision the stone was found to be large, contrary to the supposition, one should rather try to break it up, than to draw it out whole.

Knowledge as to the nature of the stone was first brought from darkness by Scheele. He found (1776) that it consisted of a special acid, lithic acid ("Steinsäure"), and contained no lime. Later, phosphate of lime was discovered in it. Then Fourcroy, who distinguished twelve kinds of stones according to their composition, and Vauquelin (1799), found lithate of ammonia, oxalate of lime, silica, phosphate of ammonia and magnesia, and an animal matter which was regarded as a "glutinating mucus," which held together the constituents of the concrement. Pearson changed the name lithic acid to uric acid. Water rich in calcareous earth and selenite in connection with humid air among other things, was announced as the genesis of bladder stone (Saucerotte) and the basis of every bladder stone was sought in small renal stones (Schmucker).

Surgeons were not inexperienced in *catheterism.* Heister considered the silver catheter as the best and thought that a thick one slipped into the bladder more readily than a thin one. His variously formed instruments were very similar to those of the present day, only the apertures on both sides were larger and longer. In cases of suppression of the urine and paralysis of the bladder, to make possible a longer retention in the bladder he used a flexible catheter, which consisted of a spiral-formed silver wire, an idea of Solingen, which later came into use through Flurant, but which was not favored by Richter. Petit recommended a catheter which, when open, could be closed by means of a button situated at the end of the wire, and gave it an S-shaped curve corresponding to the course of the urethra. For injections the posterior end was enlarged in a funnel shape, in order to accommodate the mouth of a syringe (Garengeot and Brambilla). Theden has the merit of the introduction of the elastic catheter into surgery. He had a fine gold wire insulated with silk, wound in a spiral around a thick wire and washed with a solution of caoutchouc. He said in favor of these flexible instruments that they were easily inserted by unskilled hands and could be left in position for a considerable time. Richter at first praised them, but later made the discovery that they were too easily worn out, insomuch that one patient with suppressed urine, for example, found ten necessary within eight weeks, therefore at the price of six thaler each, the expense was too great. They were displaced by the catheter of Professor Pickel of Würzburg (1783), which consisted of silk cylinders which were woven over a probe and covered with a varnish. These lasted longer and were cheaper (five for a louis d'or). The rules for the insertion of the catheter, as Richter gave them, are still valued. According to him the most important was, never to apply force. The master turn (tour de maître) arising from the charlatanry of the lithotomists of the Middle Ages, to conceal from the bystanders, under complicated manipulations, the introduction of the catheter, he regarded as injurious, but if the catheter would not come out over the prostate, recommended one whose point was bent farther, to the length of about an inch, hence the model of the Mercier instrument.

(To be continued.)

SOCIETY PROCEEDINGS.

Chicago Academy of Medicine.

Stated meeting, October 15, 1897.

(Concluded from page 1270.)

Dr. G. Frank Lydston in the Chair.

REST CURE IN HYSTERIA.

Dr. H. C. B. Alexander—The value of the rest cure in hysteria will turn entirely on the organism attacked. In a degenerate organism or in one with an acquired neuropathy due to traumatism or secondary to constitutional disorders, infections and otherwise, hysteria under the strict Weir Mitchell type of rest cure (especially as conducted by trained nurses without medical supervision) does not do well as to ultimate mental outcome. With the rest cure modified as far under medical supervision as to introduce a healthier mental tone, even this type may improve very decidedly. Improvement in general nutrition without mental improvement is often mistaken for cure of hysteria. As the disorder is practically accepted by the vast majority of neurologists as a psychosis with nervous expression such "cures" are physiologically illogical and do much to injure medical science in popular estimation since they support the claims of the faith healers and other charlatanic enthusiasts. The hysteric inhibitions need strengthening, and unless this be done nothing is permanently accomplished. The hysteric, in my experience, is peculiarly susceptible to suggestion so far as individual symptoms are concerned. Of this, the case of blistering by suggestion which I reported to the Academy some years ago[1] was an excellent illustration. This element of suggestion constitutes at once one of the dangers and the benefits of the "rest cure." Too frequent concentration of the patient's mind on a symptom or group of symptoms tends, under the most simple principle of association, to produce exaggeration or fixity of these symptoms through suggestion. The opposite course has decidedly beneficial effects. This constitutes one of the dangers of the "trained nurse" in this method of treatment. Her desire for objective symptoms due to methods taught as to so called precision leads to the frequent suggestion of new symptoms to the nosophiliac mind of the hysteric. The same fact should rule diet and medical treatment. In the type of hysteria developing upon a nervous adynamia or brief neurasthenia the rest cure gives undeniably good results but, as in the deep neuropathic or degenerate types, its essential principle of seclusion from improper sympathy, medical or otherwise, must be rigidly carried out. The defects of the rest cure largely arise from the violation of this essential principle. The "cure" should always be under the care and supervision of a physician. "Trained nurse," "rest cure," are no more quackish than other practices of medical principle by [illegible]. To them are due the disrepute the rest cure has obtained with many excellent practitioners. Removal of the patient from the morbidity-manufacturing atmosphere of home is a necessity, but it is no improvement to fling the patient into a lay atmosphere which will manufacture a similar atmosphere by the showy lay use of instruments of precision in the search for symptoms which will undoubtedly be furnished abundantly under such conditions by the hysteric. Diet, medicine, etc., during the rest cure must be suited to each case.

SUGGESTION IN HYSTERIA.

Dr. W. X. Sudduth—I was not here early enough to get Dr. Bannister's definition of hysteria; I shall therefore, take the liberty of giving one of my own. Hysteria is a pathologic mental state in which there is increased suggestibility accompanied by lack of emotional control. This being the case, the hysteric state should be very amenable to suggestion; and that is the trouble with it. It is so amenable to suggestion that we get little or no permanent results in the treatment of the disease by suggestion alone. The Charcot school held that hysteria was one of the manifestations of hypnotic suggestion and that necessarily all good hypnotic subjects were hysteric, but I find in the use of suggestion that hysteric patients are the very worst, so far as permanent results are concerned. I would rather treat any other patients than hysteric ones so far as permanent results are concerned, because these patients are amenable to suggestion from all sides. Anything that stands for an idea in the mind of a patient is a suggestion. Whether it be verbal or physical, external or internal, that is suggestion given by some one else, or auto suggestion.

In the treatment of hysteria I find that I get much better results where I couple physical exercise as a basis for the administration of suggestion, putting the patient through a course of "psycho-physical culture." If he will carry out the breathing and physical exercises to be given, the results obtained by these exercises are more permanent than when suggestions are given in any other way. In fact, where emotional prodigality exists, as it does in hysteria, one of the surest ways of controlling it and redeveloping the will power is through a series of physical exercises, muscular training, rhythmic breathing, systematic habits, and a regular military discipline, such as I put my patients on. Accompanying these exercises suggestion is used from which, to my mind, we may confidently expect benefit in proportion to the thoroughness of the system employed.

The statistics given by Dr. Coolidge justify suggestion, if applied in this way, in the treatment of nearly all forms of hysteria. Hysteric cases are difficult to handle, and it requires a great deal of patience to get good results. The very amenability of patients to suggestion is apt to give rise to a recurrence of hysteria. Unless the patient follows out some such line of psycho physical culture you need not expect permanent benefit to be derived from the use of suggestion in the treatment of hysteria.

GENERAL REMARKS ON HYSTERIA.

Dr. James G. Kiernan—In dealing with the question of hysteria, the diagnosis is of necessity the first factor requiring consideration. My experience leads me to doubt whether clearly defined demarcations can be made between hysteria, neurotic states and neurasthenia, yet upon such demarcations must turn the questions of treatment and prognosis. In my opinion a neuropathic state may be either an expression of hereditary defect or of some systemic shock from traumatism, or secondary to the great systemic disorders. If nerve-tire and resultant neurasthenia be grafted on such a neuropathic state, either inherited or acquired, the resultant will be a condition which in many instances neurologists can not demarcate from hysteria even when this last occurs in a scion of a degenerate stock. Hysteria is not the clear cut symptom-complex of favorable prognosis which many practitioners and neurologists accept as a type. Globus hystericus and unstable emotionalism have not the pathognomonic symptoms that popular medical opinion assigns to them. Either or both may be an expression of an attempt to suppress a deep emotional state and have nothing pathologic about them at all. Usually these two symptoms represent all that there is in the popular conception of hysteria and the gravity of that disorder is thus beclouded into a triviality. From this standpoint it is not difficult to see how hysteria comes to be regarded as due to civilization. Unrestrained shallow emotionalism is characteristic of a lower grade of culture. Civilization tends to restrain emotional expressions, but this implies increased evolution of inhibitions. The absence of these inhibitions would therefore imply a lower grade of culture not due to civilization, but survived in it from savagery with whose sins civilization is so often charged by a certain school of pessimists. Sexual perversion, like hysteria, was said even by Krafft Ebing to be a product of civilization, but an American physician, A. B. Holder, showed that it had existed from time immemorial among the Indians of the Northwest, and that each tribe had its own term for the practice, showing that it had originated within the tribe. If it had been otherwise the practice would been have denominated by a loan word. On the Indian reservation in the interior of New York are both civilized members of the Six Nations whose daughters play pianos as well as those who perform fetichic rites at the feasts of the "White Dog." Hysteria is more common in the women of these last than the first. The dances at the feast of the "White Dog" are marked by hysteric phenomena closely akin to those of the dancing mania of the Middle Ages. In the nineteenth century, speculative changes often lift the lower classes, intellectually speaking, into the plutocratic classes. It is hence not surprising to find hysteria exceedingly common among the "higher" classes so constituted, but civilization does not manufacture this hysteria, free from it.

---

[1] Journal of the American Medical Association, Vol. xxiv.

Dr. Butler brought out an excellent point in referring to the case of the eighteenth century servant girl, who had hysterics which might be emulated by some of our fine women of today. She, like hundreds of others were, might be raised to wealth, but civilization and culture would not cause her hysterics. Hysterics I find come from all the nations of Europe, and in the main from the lower stations in life rather than the upper.

A Bohemian general practitioner once insisted that hysteria was rare in Bohemia. I got an explanation at one consultation why, in his opinion, it was rare in Bohemia. He asked me to see a girl of 16 years, whose mother would not let her go to work, but wanted to keep her at school, whereupon the girl had a typical hysteric convulsive attack. She later became paralyzed and anesthetic on one side and had hysteric mutism. On inquiring into the family history I found the mother was similarly affected during her girlhood by the same exciting factors, and that the grandmother had been likewise affected. When the girl was allowed to go to work the convulsions and hysteric hemiplegia disappeared. The practitioner had looked upon these from his ordinary conception of hysteria, which means emotional irritation, globus hystericus, etc. After that he saw a number of cases of hysteria. His opinion in the matter was in marked contrast with that of another general practitioner who had a large clientele among a very hard working class of people, and who observed many cases of hysteria with varied manifestations. He brought me, on one occasion, to see a woman suffering apparently from gallstone colic. She had jaundice and a slightly elevated temperature, but when her husband promised her a new dress the condition disappeared. That woman had worked in the fields in Germany. She had a good many of these attacks To attempt a demarcation on the ground of apparent difference in the sex or social condition as a method of diagnosis is futile. As regards sex I must confess I would like to find out the difference between neurasthenic cases which have been built upon a pathologic basis and hysteria; when it occurs in the man, and when in the woman I can not make the diagnosis I get the anesthesia, the visual field disturbance, and every now and then hysteric ptosis in the man. In attempting to draw this line we are drawing it rather on older ideas than on data that are more obtainable. We are too apt to look at the man who is a neurasthenic as a pure hypochondriac The subjective results are more frequent than the objective, and they do not vary one iota in my experience from typical hysteria I have never been able to do much with the so called hysteric zone, although I have tried repeatedly to do so One man had a notion which started with his testicles A grave hysteric condition could be set up from that source

With reference to the question of traumatism in these cases it is a grave condition, and one that is not easily recovered from There is often a marked change of character in previously healthy people, which does not subside on receipt of payment of certain damages, as we are frequently informed by gentlemen who devote themselves to railroad interests. The condition continues a long time after. I have seen a marked case manifesting true symptoms of hysteria in a man who fell into the hands of an orificial surgeon for these four years after injury. This man could not be accused in the slightest degree of desiring damages He was a builder of bridges on the Mississippi. He had been knocked into one of his own boats by his own derrick, had sustained a fracture of the scapula, and it was also suspected that he had sustained some spinal injury. Among the symptoms that were decidedly marked after the accident were retention of urine and anesthesia on one side. The urine, before I saw the man, had been drawn with a catheter I made a careful examination and my opinion was against spinal injury, but in favor of general traumatic shock. I told the man he would be able to pass his urine that night without a catheter, and he did it But that man's character completely changed. He improved for a while. That man is now an hysteric, and I doubt if he will ever return to the original condition he was in at the time of the injury.

With reference to the mental condition of the hysteric, he exhibits one of the characteristics of degeneracy, namely, anesthesia of moral sense.

I had hoped Dr Moyer would be here to take up the forensic relations of hysteria, because hysterics sometimes commit acts with extreme cold bloodedness, and without apparently sufficient motive. I remember the cases of a girl who poisoned four members of a family. She was a hystero epileptic. She committed this act with the utmost coldness, without any apparent motive except a slight scolding, and she was only detected by accident. Another phase of the mental state with which physicians are familiar is hysteric accusation, and this has more than once landed many an innocent person into a penal institution or State's prison. In our State we had a case where a hysteric came near landing four men in prison. The community was very much excited over the supposed assault, but the story was too much even for a country jury in its final contradiction. It is the safe rule in an accusation of criminal assault to take into account the possibility of the accusation. With regard to the minor forms of hysteric mental disorder, they are characterized by emotional instability, by emotional irritability and by a large number of hallucinations and other conditions that are in no small degree the product of suggestion. in the grave disorders there are mixed religious and erotic symptoms; women who have seen the Virgin and angels and have talked to them are in a number of cases hysteric.

There is one work in pathology that might be read with advantage, namely, the hagiology. St. Theresa, for example, was a most magnificent case of hysteria. She used to have one part of the time a divine ecstacy which made her have a convulsion and kick everything out of bed. Then she used to faint and her soul would mount up to heaven. She had seen her celestial spouse and would give the usual mixed story of the hysterics. This grave hysteric condition does not tend to pass into dementia, but it is nevertheless a destructive condition as far as the mental state is concerned.

The visual field side has been much discussed and needs little further reference. Charcot claimed, in 1888, that all so called hysteric unilateral paralysis of the facial, lingual and oculomotor muscles are in a reality hemispasms. This view of Charcot was later abandoned by him and his followers. A case of mine observed some four years ago tends to justify this abandonment. The patient, since this case was first observed, has repeatedly come under my observation for the like condition, which has remained "cured" for a longer time than usual after the correction of certain errors of refraction by glasses. The case is as follows: The patient, a 33 year old married multipara, comes from a family rife with neurotic taint. Neuroses of various types are frequent in this family for three generations. One sister has periodic attacks of nymphomania, whose morbid nature she recognizes and is therefore able to control. The other children suffer from cerebral phenomena from very slight causes. One brother has had infantile hemiplegia with athetoid phenomena. There have been numerous children for three generations, the greater proportion of whom died in infancy. The present patient has visceral neuroses, simulating at times peritonitis and gallstone colic and attended by pyrexia followed by apyretic states, when the temperature falls from 109 to 90 degrees in a few hours without corresponding constitutional disturbances. Paralyses and local anesthesia are easily produced in this state from suggestion.

On one occasion discolorations of the skin resulted from an accidental suggestion that the skin looked slightly reddened at the seat of a paresthesia. The patient had an attack of "visceralgia" simulating gallstone colic. This left her much exhausted, and in this state the suggestion was made by a neighbor that her eyes looked weak whereupon slight amblyopia resulted, followed by double ptosis. The "visceralgia" disappeared under what was chiefly moral treatment, but the ptosis persisted for some weeks. One day while the patient was relating her symptoms a window fell and she passed into a hypnotic state While in this state the suggestion was made that her ptosis was under full control of her will and that she would hereafter be able to control it. On awakening her from the hypnotic state the ptosis and amblyopia disappeared.

The last attack occurred under the following circumstances: The patient while East had been treated for a headache by the correction of refractive errors through glasses. Soon after her return to Chicago she suffered with a very obstinate suboccipital headache. Through much talk by her friends she was persuaded that this headache was of optic origin and that the glasses had been improperly fitted. She was found to be badly constipated. The persuasion, however, that the eye had been improperly fitted with glasses continued. She finally had a recurrence of the old symptoms of ptosis and amblyopia. This condition, however, disappeared with the disappearance of the headache, which yielded very rapidly to dietetic treatment and cathartics. Since this time (nearly a year ago) there has been no return of the ptosis and the patient has not complained of either eye strain or headache.

If I were to discuss the subject from a therapeutic standpoint I should be exceedingly careful in giving anything but a very guarded prognosis in cases of traumatic hysteria, and some of the graver forms of the affection. I should also use a great deal of care in giving a prognosis from the results of the rest cure treatment in either one of the two forms of the disease. There is no doubt that the rest cure has done good in cases of hysteria, but most physicians who have seen cases find that it has likewise done a great deal of harm, and has given patients a chance to brood and form fixed illusions and ideas when carried out in routine fashion.

As regards the question of epilepsy, there is one point that puzzles me, namely, the differential diagnosis between the epileptic state in which hysteria occurs and hystero-epilepsy. In well defined cases there is no difficulty experienced in this regard. But take the average text-book and the only diagnostic point is drawn between a grave hysteric attack and a grave epileptic attack, and the hundreds of minor epileptic disturbances that simulate hysteria on the one hand and the hundreds of hysteric disturbances on the other are ignored. The difficulty is further enhanced by the large number of epileptics who have entirely hysteric attacks. I had a case under my care, an undoubted epileptic, and yet of the three attacks he had while under my observation, two were genuine hysteric attacks, the third was a true epileptic attack. For a long time I was puzzled about certain beneficial therapeutic effects, until an explanation was found in the hysteric condition.

With regard to the diagnosis, the temperature may be of some avail, but the physician who watches epileptics in an insane hospital will find temperature disturbances that closely simulate those observed in the hysteric.

A point that may be covered by some of the subsequent speakers, one which is now being raised by certain neurologists, is as to whether the presence of certain tests, like the ankle clonus, are purely characteristic or indicative of organic disease. There have been two or three cases that look very suspicious in that direction. This raises another point to which a number of neurologists are opposed, but on which I am inclined to believe with Charcot, namely, that secondary to prolonged localized hysteria we may have local spinal or cerebral pathologic changes set up. Two-thirds of the secondary changes which occur in certain acute psychoses are due to biochemic lesions. I see no reason for doubting the cases Charcot has published. He published his first case in 1867, in which the spinal lesions found were not changed to hysteria, nor did he attribute hysteria to them, but he believed that they were the secondary results of disease consequent on hysteric contractions.

Dr. Kuh made a statement regarding epileptics which I have heard made quite frequently, that the epileptic pathologic findings are primary. Spitzka and myself made quite a series of careful examinations, examining brain after brain of persons not dements, and found teratologic lesions due to a degenerative condition, but no microscopic or macroscopic lesions.

I can not fully agree with Dr. Sudduth as to suggestion. As to its effect on the disease hysteria itself I admit his position, but suggestion has a most potent effect on causing and removing symptoms. The literature of hysteria is full of such instances.

OPHTHALMIC RELATIONS OF HYSTERIA.

Dr. C. P. Pinckard—As we all know, eye symptoms may be very prominent in the clinical history of hysteria. They may be briefly divided into disturbances of motion, disorders of secretion, disorders of sensation, disturbances of sight, and abnormal sensations.

1. Strange to say, paralyses are not at all common, while spasms, on the other hand, are very frequent. An exception may be made, however, in the levator palpebræ, which is frequently paretic and not associated with other pareses. According to Charcot, it is particularly frequent in children. The next most common symptom in the muscular apparatus is a paresis of the abducens, or more probably a spasm of the abducens. Of the internal muscles, pareses of the ciliary occur, but the diagnosis is difficult. Paresis of the iris is rare. Blepharospasm is often observed, and a rhythmic twitching of the lid is said to be very characteristic. Variation in the size of the pupils is frequent.

2. Among the disorders of secretion, epiphora is frequent; edema and sweating also occur. They begin and disappear very suddenly, and may be transferred from one side to another by means of the contact of magnets, acids, etc.

3. Of sensation, anesthesias of the skin of the lids, temples, conjunctiva and cornea are very frequent, with or without retinal anesthesia. Paresthesias are also often observed, such as hyperesthesia of the lids, conjunctiva and cornea, with or without photophobia. Pain is very common, especially those pains beginning in the eye and radiating toward the forehead, temple, teeth, etc. These may occur with or without efforts at accommodation. At times tenderness is present in the ciliary regions.

4. The most important class, however, is the disorders of sight. According to Charcot, a pathognomonic sign of hysteria is the concentric narrowing of the field of vision with more or less impairment of central vision and of color perception. This, as a rule, is associated with anesthesia of the conjunctiva and cornea. This disturbance of the sight is usually unilateral, but if it be bilateral it is more marked on one side. Unilateral amblyopia is much more common than complete blindness, but double amblyopia is still rarer. The boundaries of the field for the different colors may be entirely abnormal, so that the curves of the different colors may cross each other, or the order be reversed. Charcot has said that hemianopsia does not occur in hysteria, but others, as Landolt and Glorieux, have denied this. Diplopia or polyopia, either unilateral or bilateral, is a rare symptom, but occasionally occurs. Complete blindness is much more common in one eye than in two, but bilateral blindness is not so rare as it would seem. Within the past three months I have had two cases of bilateral complete blindness, one in a woman 36 years, the other in a child of 14 years, in both of which cases the attacks came suddenly and disappeared as suddenly upon suggestion.

5. Of the abnormal sensations the most important one is the so-called *audition colorée*, that is, certain tones or words produce a coincident vision of color. Still rarer, where certain colors perceived cause coincident tones.

The case of ptosis, reported by Dr. Kiernan, without other symptoms in the eye, is very characteristic. As was said before, this symptom occurs more often in children than in adults.

A diagnosis of hysteric symptoms from symptoms simulated is at times very difficult, and can only be positively made by association with other symptoms in other parts of the body.

PRACTICAL NOTES.

Incompatibility of Hydrochlorate of Cocain and Nitrate of Silver.—If cocain is to be used with nitrate of silver, the nitrate must be used, instead of the hydrochlorate, as the latter causes an insoluble precipitate of silver to be deposited.—*Nouv. Remèdes*, November 8.

Sterilization of Catgut.—Rajewski recommends that the catgut be sterilized while it is being manufactured with a 1 per cent. solution of formaldehyde. This sterilizes the interior, and superficial sterilization is sufficient after this. He considers chemic methods of sterilization more reliable than physical.—*Cbl. f. Chir.*, November 6.

Painful Dentition in Infants can be relieved by frequently washing out the mouth with a 1 per cent. solution of chloral hydrate, which is antiseptic as well as analgesic. Rub the gums to soothe the pruritus with the following: Cocain hydrochlorate 15 centigrams; chloroform, 1 gram; glycerin, 20 grams; essence of roses, 6 drops.—*Presse Méd.*, October 20.

Prophylaxis of Chapped Hands.—After washing the hands with non-irritating soap, rub in the following lotion and allow it to dry on the hands. It is especially recommended to physicians and surgeons. Alcohol, 80 grams; glycerin, 35 grams, rosewater, 30 grams; salol, 2 grams; tincture of musk, 2 drops.—Morel-Lavallée in *Gaz. Méd. de Liège*, August 22.

Mother Solution of Formol for Surgical Antisepsis.—The disagreeable odor of formol is disguised if prepared as follows: Alcohol solution of formol at 40 per cent., 25 grams; tincture of eucalyptus, 5 grams; ethyl alcohol, q.s. to make 200 c.c. Each teaspoonful contains 25 centigrams of formic alcohol: 1 to 4 teaspoonfuls to the liter of water.—A. Reygasse, in the *Semaine Méd.* of November 24.

Oxygenated Water in Psoriasis, Otorrhea and Plugs of Cerumen.—E. Luton reports a severe case of psoriasis cured with injections of an oxygenated serum as follows: 10 per cent. solution of sodium phosphate, 75 grams; oxygenated water, 20 volumes, 25 grams. Local applications of oxygenated water assisted the cure, which was surprisingly prompt and complete. A small quantity of oxygenated water dropped in the ear will soften the hardest wax plugs so that they can be syringed out without difficulty. The efficacy of oxygenated water in purulent chronic otitis, with or without mastoid complications, has already been proclaimed in America and Belgium. Buys and Lebarre had only three negative results in sixty cases treated with it.—*Semaine Méd.*, October 27, November 10 and 17.

Treatment of Epidemic Cerebrospinal Meningitis with Injections of Sublimate.—Nineteen recovered in twenty-seven cases, all treated with a daily subcutaneous injection of sublimate, varying with the age from 5 decimilligrams to 1 centigram. Improvement was observed after the second or third injection; the pain was relieved so that the patient could sleep; consciousness returned after the fifth or sixth, and the fever gradually subsided. Four to twenty-four injections were required.—B. Angyan of Budapesth in the *Semaine Méd.*, October 20.

Abortive Treatment of Influenza with Calomel.—Freudenthal has been successful in aborting influenza with 10 centigrams of calomel twice a day (men) and 5 centigrams three times a day (women), administered in the first or second day of the attack in epidemics of grip. The temperature falls in six to eight hours, the neuralgic pain subsides and the cure is complete in forty-eight hours, or in a week when the treatment was not commenced until the third day. He combines antipyrin or phenacetin with it if there is much pain, wet packs of the thorax if the fever does not subside, and sodium iodid if there are respiratory complications.—*Presse Méd.*, November 6.

Treatment of Chilblains with Chlorinated Lime.—This substance passes through the epidermis and soothes the inflammation beneath, applied in a salve gently rubbed in for five minutes at bedtime and covered with an impermeable bandage (Rp. Calcar. chlorat., 1.0; Unguenti paraffini, 9.0; M. f. unguent. subtiliss. D. in vitro fusco. For external use). This salve has often cured the obstinate and disfiguring redness of the tip of the nose in women during the cold weather. The chlorinated lime must be fresh and effective and the salve smell strong of lime, otherwise it is worthless. C. Binz, *Therap. Woch.*, October 24.

Compression of the Nerves to Relieve Whooping Cough.—A. de Miranda announces in the *Semaine Méd.* of October 20 that compressing the vagus at the neck checks the vomiting in this disease, and that compression of the superior laryngeal rapidly calms the paroxysms of coughing. The family can be easily instructed how to perform the compression. In the early stages of the affection the bronchi are full of mucus and the cough must be allowed its course, but later the compression will be found practicable and effective. He also reports the cure of one case of uncontrolable vomiting in pregnancy by compression of the cervical portion of the pneumogastric.

Protargol.—Prof. A. Neisser states that he has never obtained such certain and permanent cures in gonorrhea as since he commenced to use protargol. It is a fine yellow powder, a combination of 8 per cent. silver with a protein, dissolves readily and is not precipitated like the other silver salts by albumin, diluted sodium chlorid, hydrochloric acid or sodium. Its general disinfecting power is not yet established, but its efficacy in gonorrhea is beyond question. He uses a 0.25 per cent. solution, increasing to 0.5 and 1 per cent and makes three injections a day, the patient retaining the fluid five minutes after the first two injections and thirty minutes after the last, soon reducing the treatment to the one long retained injection a day. This treatment is so little trouble that it can be kept up three to four weeks and ensures a permanent cure.—*Therap. Woch.*, October 24.

Hernial Tuberculosis is the subject of an extended study by Barozzi reproduced in the *Jour de Méd. et de Chir.*, of October 25. In the twenty-two observations on record the diagnosis was usually uncertain, and the operation alone, which is the only treatment, cleared up the question. The existence of a liquid effusion, the thickening of the sac and the presence of indurated points, are the guide, as the subjective symptoms vary from severe functional disturbances, much pain and edema to merely slight discomfort. Left to itself the termination is always fatal, and the fourteen cases on record have a mortality of 21.4 per cent. Jonnesco advocates herniotomy; the resection of the diseased intestine seems risky to him in such cases. Koenig also asserts that the circumscribed lesions of the intestine have a tendency to spontaneous recovery, but the writer, Terrillon, Routier and others, consider laparotomy indicated, especially when the bacillary lesions have invaded the large peritoneal serosa.

To Disguise the Taste of Cod-liver Oil.—℞: Cod-liver oil, 400 grams; syrup of tolu, 200 grs.; tincture of tolu 12 drops, essence of cloves, 2 drops. Do not emulsify. Shake well before using. Dose: a tablespoon two or three times a day.—Bricemoret, *Rev. Méd.*, November 10.

Dangers of Arsenic in Cutaneous Diseases.—Brocq states in the *Jour. de Méd.* of September 10, that arsenic should only be administered in dry dermatoses, never in the moist kinds, as it makes them worse. He even ascribes some of the keratodermia accompanying Dürhing's disease, to the arsenic treatment exclusively, also pigment patches.—*Therap. Woch.*, November 14.

Eudoxin in the Gastro-Intestinal Troubles of Children.—Recommended by Rosenheim for chronic diarrhea in adults, Ladniewski has been testing this bismuth salt of nosophen in fifty-eight cases of diarrhea, and announces that he found it effective in some cases with mucous or purulent discharges that had resisted the usual remedies, bismuth, nitrate of silver, etc. He gives as many centigrams as the child is months old; limit, 50 centigrams, repeating the dose two to three times a day. In other forms of diarrhea it is counter-indicated, particularly in cholera infantum.—*Semaine Méd.*, November 10.

Pyramidon.—The antipyretic and antineuralgic properties of pyramidon, dimethylamido antipyrin, have lately been proclaimed by several who consider it a valuable acquisition. The temperature is gradually lowered from one-half to two and one-half degrees during the two hours after the dose (0.2 to 0.6 gram), and slowly rises again in four to six hours. It has also a marked soothing effect. Hornoffer tried it in forty-five cases of phthisis, also in pneumonia and typhoid, and states that there are no inconveniences from its use, which can be kept up for months without injury or lessening of the effect. It proved ineffectual in ischias, but cured trigeminus neuralgia and headaches, the latter in one dose. (*Berl. Klin. Woch.*, No. 35). Two cases of trigeminus neuralgia cured with it were reported at the Congress of Naturalists and Physicians. Feuerstein has found it possible to prevent fever altogether in pulmonary tuberculosis, by the administration of 0.6 gram during the hour in fractional doses. He confirms its harmlessness. No benefit seems to have been derived from it in rheumatism. *Therap. Woch.*, Nos. 41 and 44.

Reduced Mortality from Pulmonary Tuberculosis.—Good effects have already begun to show themselves in New York City as a result of the compulsory notification of cases of pulmonary tuberculosis to the Board of Health. In a report to Mayor Strong, this Board declares as a result of three years' special effort to stamp out pulmonary tuberculosis that the disease is a distinctly preventable one; that it is not directly inherited; and that it is acquired by transmission from the sick to the healthy. Deaths due to pulmonary tuberculosis are now 30 per cent. less that they were twelve years ago. The Board recommends that the law should be amended so that all cases of pulmonary tuberculosis shall be reported to it; that rooms of a patient dying from the disease shall be disinfected; that special care be used in transporting tuberculous patients on railroads, steamers, etc. The general dissemination of a knowledge of the foregoing fact, in conjunction with an application of the principles of an enlightened hygienic will do much not only to further diminish the mortality from tuberculosis but also to restrict its general prevalence.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, 100 Washington St., Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly Journal of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the Journal office.

All communications and manuscript of whatever character, intended for publication in the Journal, should be addressed to the *Editor*, and all communications relative to the business of the Journal, proof sheets returned, or in regard to subscriptions, should be addressed to The Journal of the American Medical Association, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this Journal.

SATURDAY, DECEMBER 25, 1897.

IS THE APOTHECARY SHOP DOOMED?

Industrial evolution, as well as professional evolution, is constantly changing the relation of individuals to each other. The apothecary shop was originally the medicine-room of the physician. Galen himself is supposed to have used the word, deriving it from the Greek *apotheka* meaning a store or magazine. It was not until the time of Henry VIII. that apothecaries were recognized as distinct from the medical doctors. They were incorporated in 1606 together with the grocers, but later on had a separate organization, and since then have become more and more specialized. Today another change seems to be taking place among them. The manufacturing pharmacist with his large factories and hundreds of workmen, is assuming here and there the duties of the dispensing apothecary.

On the one side the physician has his medicines ready made; his pills, tablets, coal-tar combinations, organic compounds, elixirs, etc., are used as they come from the manufacturer. The apothecary dispenses them as the grocer sells baking powder and soap. No skill is necessary to fill a prescription for "Aunt Martha's Soothing Syrup" or "Roberts' Elixir of New Life." On the other hand, the science of therapeutics is becoming simplified; no twenty-ingredient mixture as in old times; not so much dosing; more expectant treatment; and the pill manufacturer is putting up cough syrups and tonics and fever mixtures to please the taste of the most fastidious.

Where is the apothecary to go? Is he to become a vendor of toilet articles and fancy crockery? Is he to be the commission agent for the pill manufacturer? Or is he to set up a medical advice counter and revert to the old surgeon-apothecary of the Middle Ages?

In the cities, many druggists study medicine and advertise *advice* and drugs for a nominal fee, and, on the other hand, many doctors buy a case of tablets and mixtures and dispense their own drugs. The manufacturing pharmacist in all probability is going to stay and to enlarge his domains. His agents will become more obtrusive, physician's samples will be left in greater numbers, and he will have his retail agents on every corner. Perhaps this is not bad; perhaps it will insure greater uniformity in quality. The large manufacturer can afford to test all the drugs he purchases; he can command the best skill in manufacturing; he can obtain greater accuracy; his pharmacists are not bothered by retail customers, or talkative friends; they need not be overworked and underpaid.

The corner drug store with its boy and one clerk, and its thousand and one things requiring attention, its soda water counter, window cleaning, unpacking of goods, etc., is not in a position to fill prescriptions accurately. The large factory with its labor divisions is surely in a better position.

In the evolution of the trade, the manufacturing pharmacist must supplant the small drug store just as the department store supplants the small dry goods shop.

Even at present very few pharmacists do more than act as agents for the wholesale druggist. They buy their tinctures and extracts, pills and plasters already made. Their infusions are water-diluted extracts; their waters are mixtures of essences. They have not the time nor the means to make their own preparations, and the chances are that the crude drugs they would make them from would be beneath the standard.

And then they must load their shelves with a dozen makes of pills, a hundred and more new remedies that the physician tries once and abandons. Surely the lot of the apothecary is not a happy one. Can the doctor do anything for him? We hardly think so. Economic reasons are at the bottom of it, and the druggist must go the way of the tailor, the shoemaker and the cigar-maker. His education must fit him for the laboratory of manufacturing apothecary and not for the corner drug store.

THE DISINFECTION OF BOOKS.

It has long been recognized by boards of health and others that the disinfection of school books and library books was a peculiarly difficult problem. We therefore note with pleasure that Dr. J. S. Billings of New York City has taken the problem in hand, especially that which relates to the sanitation of libraries.

Attention has been called to this matter so repeatedly that many of the boards of health of the different

States have taken action and caused the State legislatures to make a criminal offense for persons coming in contact with contagious diseases to borrow books from circulating libraries. But the act is often done so unwittingly that some other means seem necessary in order to combat the evil.

Be this as it may, future borrowers from New York's great library can rest assured on this head, for the trustees have already formulated a plan by which means every book that leaves the library shelves will be submitted on its return to a process of sterilization and disinfection that will free it from all its pathogenic properties. Several months ago, when the idea of the consolidation of the free libraries was but yet in its infancy, the officers of the library commissioned Dr. John S. Billings, the future director of the library, to make experiments with a view to determining how such a process could best be carried out, and it is the result of Dr. Billings' investigations that will prevail when the new library is opened.

The agent that Dr. Billings will employ is formaldehyde gas. In actual practice each book as it is returned will be placed in a double-walled box of Russian or Swedish iron, the inner wall of which is perforated, and which has a double-walled door, which will tightly close and inside of which is a false door of glass. In this box are shelves on which the books are laid, the bottom shelf being perforated and opening into a generating box. The books are allowed to remain in this box for a period of two hours, at the end of which time not a trace of live organism can be discovered. Not only does the method not injure the books in the slightest degree, but it actually rids them of the small parasites that infest morocco and calf bindings nd which prove such a source of annoyance to those who treasure up old and musty volumes.

THE TEACHING OF MEDICINE.

Medicine can be readily separated into two distinct portions; the scientific and the practical or art. The science of medicine, or better, one should say the sciences used in medicine, can be taught by the specialist whose knowledge of the practice of medicine may be very limited. Chemistry, physics, biology, physiology, anatomy, microscopy, histology, pathology, bacteriology and materia medica are capable of being taught in the class-room and laboratory without the aid of the living human subject.

These branches of science so virtually necessary to the practice of medicine should be taught by men thoroughly trained and competent; and as this requires time for which no recompense is to be had out of practice, and as the knowledge can not be acquired in practice as other specialists such chairs should pay their occupants sufficiently well to permit them to give most of their time to the study.

There would then be a goodly number of anatomists, physiologists and medical chemists who could devote themselves exclusively to these sciences, and who would be scientists pure and simple.

The study of the application of the above sciences to the cure of disease must necessarily be demonstrated on the human subject, and by persons sufficiently acquainted with the manifestations of disease by actual clinical experience to be able to do so completely.

The hospital, dispensary and private practice is the laboratory of the clinician. Every addition to his knowledge can be put to use among his patients for his own material benefit. The position of teacher is in itself a positive benefit, as it brings to him the consultations with his former pupils, and increases his importance in the eyes of the individual who might require his services.

The man who is called to teach one of the clinical specialties of medicine should, if anything, be compelled to endow his own chair, since the advantages to be derived from such a position are quite considerable from a material standpoint. In former times great men gathered about them young students to teach them the art of medicine, or some particular portion of it. And schools were often known as the school of this man or that. Such teachers may have been filled with a desire to impart knowledge, or a love of authority, or only with the hope of gain, but whatever the end, they fully realized the advantage of teaching.

Medical schools in our country are too much concerned about the practice of medicine and too little about the science. The laboratories and scientific branches instead of being relegated to the young men who regard them merely as stepping-stones to some clinical position, should be in the hands of well-paid specialists who will aim to make the subject interesting and complete, so that the student will not shirk them as disagreeable tasks to be gone through with as superficially as possible.

There will be no difficulty in filling the practical chairs without pay if it is generally understood that a consulting practice comes through the collegiate position, and the money so saved should be used to strengthen the other side of the school.

MORE MEDICAL PSEUDO-SCIENCE.

It is not very long since there was reported in the daily papers that a Washington professor, apparently not connected with any of the scientific Government bureaus, had made some remarkable discoveries in microscopic technique which were likely to revolutionize our method and greatly enlarge our range of microscopic vision. His own account of his achievements is contained in the two latest issues of the *New York Medical Times* and is of a character to perhaps deserve notice if not unqualified belief. He claims, amongst other things that by inserting the objective of one microscope into the place for the eye piece of another he is able to increase the magnification of objects to a most wonderful extent; that he is able to photograph with an infinitesimal amount of light, less than the one-hundred thousandth part of that formerly necessary; that he can make sections the thickness of one-hundredth of the thinnest section heretofore produced and can thus divide a single cell into hundreds of separate slices. To appreciate these claims one has to realize that they apparently mean that he is able to magnify the image in the first of his two connected microscopes to the extent of the magnifying powers of the second; and that his sections, assuming that the thinnest heretofore made were two microns in thickness, would be less than one millionth of an inch in thickness, or less than the wave length of the shortest visible ray of light. We would be justified in some incredulity of these pretensions, were they far less extravagant, and if not prepared to reject them *a priori* from our acquaintance with the physical laws of matter and the laws of optics one could judiciously leave them in his suspense account until such actual and verifiable results were demonstrated as would amount to something more than claims. As it is, however, it is hardly possible to do more than to charitably assume self-deception and nothing more actual than faulty reasoning and imperfect and misdirected observations.

This would be the natural and proper mode of view were these assumed discoveries all that were announced. The author of the papers in the *Medical Times*, however, goes on to lay down at length his theories which one can best describe as a mind-cure system worked up in a pseudo-scientific way. He adopts the theory that mind and vitality are one and that physiologic processes are purely mental phenomena, an old notion that has been revived as a basis for a therapeutic system possibly many times, and notably by STAHL in the beginning of the eighteenth century, but one which requires too many assumptions and too much ignoring of difficulties to meet successfully any truly scientific tests. Plausibly stated, however, and with an abundance of pseudo-scientific verbiage it may easily gain adherents, and its appearance in a respectable medical journal, of homeopathic antecedents it is true, but with a broader and less sectarian tendency than is common amongst such publications, is a matter to be regretted.

In these times when faith cure and Christian science are so much in vogue, it is not surprising that some one should seize the opportunity to bring out a system practically identical with these but without the religious auxiliaries that contribute so largely to the success of these delusions. Such have indeed their disadvantage with a certain class of minds; the liability to medical delusions is by no means confined to church goers, or the religiously inclined. Any system of hysteric therapeutics that starts out like this one with the claim that vitality and physiologic processes are simply mental processes, and that the laws of health and disease and crime are therefore all made manifest "not by faith or through mysticism and symbolism" but professedly by verified facts ascertained by asserted scientific researches, will attract a large class who would reject the same methods offered under the guise of Christian science or a faith cure. Practically it is Christian science for non-Christians, a pseudo-scientific jargon taking the place here of the religious phraseology that characterizes the other; the element of credulity is alike predominant in both.

The whole performance is simply a revival of an antiquated psychologic theory as a basis for a sort of suggestive therapeutics, supported by extravagant statements of alleged discoveries and a few commonplace but misinterpreted experiments and observations.

CORRESPONDENCE.

Department of Health Bill.

CHICAGO, Dec. 18, 1897.

To the Editor:—I was greatly interested in reading Governor Bloxham's communication in the current issue of our JOURNAL (see pages 1284–85) regarding the proposed Department of Public Health having at its head a "Secretary of Health," etc.

Permit me, therefore, to introduce briefly as I can the following additional argument as it occurs to me at this moment, in addition to what has been stated by the Governor of Florida, why such department should be created. Twice within the past five years, namely, during the summer of 1892 and the year following, the commerce of this country was materially disturbed and the lives of the people greatly endangered by a threatened invasion of *supposed* Asiatic cholera, and that more recently, yellow fever has gained entrance to the United States, namely, in 1893 and during the early autumnal months of the present year (as has already been ably stated), wherein many cities throughout the Southern States became infected with the germs of this oftentimes very fatal though *preventable* malady. Such being the case as the *status præsens* conditions exist, it is to my mind not impossible that a repetition of these and kindred diseases of pestilential origin and character may in future invade the United States from foreign shores, and its ravages again result in the loss of many precious lives, a panic among the living (*refugees*), as well as a serious menace and great financial loss to the commercial welfare and industrial interests of our country.

It appears to me, therefore, that every medical society, and perhaps other scientific bodies throughout our land should heartily approve and give their unqualified indorsation to the Department of Public Health bill that has been prepared by the special committee of the AMERICAN MEDICAL ASSOCIATION, and as such was unanimously adopted at the semi-centennial meeting of said ASSOCIATION at Philadelphia in May last, and which was subsequently unanimously *accepted* at the twenty-fifth anniversary (annual) meeting of the American Public Health Association held in the same city in October.

As many associations have already placed themselves on record "by endorsing this bill," the profession as a unit is certainly *uniting* in its manifestation of having the utmost confidence in the ability of this special committee into whose hands this matter was intrusted, and I wi her t ing that any additional amendments to said bill should meet our hearty approval so long as the purport of its original intent and meaning shall remain unchanged and the amendments are germane to the bill, for we may not be able to get the bill enacted exactly in its present form and it may become necessary to make some minor changes, etc.

I am also reminded that the holiday season is approaching, and that many of our Senators and Representatives will "go home" on a visit at this time. This will afford "us" a splendid opportunity to personally respectfully request of our friends, our National legislators, that they carefully consider "our" Department of Public Health bill, with the view that favorable action will be taken by them toward passing this already too long delayed measure. And why should there not be a Medical Secretary or a Commissioner of Public Health, to be on a parity and rank with equal dignity as the various secretaries of the other departments of the Federal Government?

Why should the Secretary of the Treasury be longer expected to (nominally) remain at the head of the hygienic welfare of this nation? The answer is, We are too great and have outgrown such ideas.

In conclusion, I trust that Congress, during the present session, will legislate upon this question for the "welfare of the people" as provided in the Constitution of 1787, adopted in 1788, and that every physician throughout the country who has not already personally interviewed his Representative or United States Senator and discussed this topic with him, will do so, by correspondence or otherwise, within the near future, and appeal to him to vote for said bill.

With best wishes for our Journal also in its efforts in this (the right) direction, and for its future prosperity, and a very merry Christmas and bright New Year to all its readers, I beg to remain, Very sincerely yours,

Liston H. Montgomery, M.D.

Concerning Rates to the Denver Meeting.

Sioux Falls, S. D., Dec. 16, 1897.

To the Editor:—Dr. J. F. Jenkins in the Journal of December 11, thinks that if the Committee on Transportation could obtain the same rates to the meeting of the American Medical Association that other less important bodies get, we could have at least five thousand physicians present at the Denver meeting next year. Now, we have been informed that the doctors formerly had all they could ask for in the way of rates, until they abused their privileges. The railroad companies finally kept tab, and discovered that in one year, free transportation to the amount of about $60,000 had been called for and used to go to places other than the Association, over and above that actually used in good faith. The railroads thereupon cut off free transportation over each other's lines to their surgeons, thereby punishing the innocent with the guilty.

Hence, the doctors have some of their own numbers alone to blame in that direction. If the committee could induce the railroad companies to grant transportation to their surgeons, under such restrictions that the companies could not be imposed upon, hundreds of railroad surgeons would attend who could not otherwise afford to do so.

The incidental expenses outside of transportation amount to quite an item to the average country doctor.

Our experience with railroad companies is that they appreciate good, honest service, and are liberal with those who do not abuse their privileges. It is certainly to their advantage to have their surgeons use every available means to improve themselves professionally.

It is true, the American Medical Association includes all regular physicians in good standing who wish to join, and is in no way intended more for one branch or class of the profession than another; yet the existence of two national associations of railway surgeons, besides numerous smaller ones, demonstrates that that class of physicians are active and progressive; men who would not only be glad to avail themselves of the benefits of the American Medical Association, but would make valuable members as well.

Yours respectfully, A. H. Tufts, M.D.

PUBLIC HEALTH.

Prophylaxis of Yellow Fever.—Lacerda states that the epidemics of yellow fever in Rio de Janeiro are due to the periodic revivification of the germs of yellow fever in certain permanent foci in the interior of houses and the holds of ships, where they propagate, favored by dampness, darkness and filth. They can not live any length of time in sewers nor in open water, nor anywhere exposed to the sun. His conclusions were adopted by the Academia de Medicina, which proclaimed that the extinction of these foci in Rio de Janerio is practicable and necessary.—*O Brazil Médico*, October 22.

Sanitation of Railways and Steam Vessels.—The *New Orleans Medical and Surgical Journal* states that the State Board of Health of Louisiana has adopted resolutions calling attention to the present lack of sanitary measures in vogue on public carriers, notably steam vessels and railroad sleeping cars. The necessity for reform in this particular is too glaring to need defense. No one who travels fails to observe the offence to health and ethics which exists on the steamship or sleeping car. The wash basin is used by the porter for his own toilet, and it is not an infrequent thing to see the cuspidors washed out at the same font. From the standpoint of health, it is familiar to all that no provision is made for those suffering with tubercular affections or with other ailments. We have seen the syphilitic, in acute eruptive stage, use the common drinking-glass, the toilet articles and eating from the buffet crockery. Not long since a lamentable instance was related to us of a woman dying of tuberculosis, on her way to New Orleans, making the car uncomfartable by her spells of coughing and rendering the atmosphere unbearable by the emanations from the decomposing lungs. The Pullman conductor relating the incident, deplored the fact that no provision was made for the separation of such cases. Resolutions can only direct intelligent thought at the remedy, but peristent effort in directing attention to the necessity for some remedial measure must result in its application. State legislatures have it in their power to compel sanitary measures through their State Board of Health, and there is no reason why the legislative action should not go farther in compelling provision for the hospital accommodation in transit for such cases as the above.

Fumigation of the Domicile by Corrosive Sublimate, followed by Sulphur.—The October number of *Public Health* contains the following annotation regarding the disinfection of rooms after contagious disease. Professor Koenig of Goettingen, in a recent article, says that at one time, while he was practicing medicine in Hanau, he suddenly discovered that his bed room was thickly inhabited by obnoxious insects. A friend assured him that he could easily get rid of the pests and proceeded to fumigate the apartment with corrosive sublimate. The success of this measure was most gratifying, and when the room was opened the dead bodies of various kinds of insects were seen strewn about the floor. This incident led the professor to hope that the same means would be effectual in destroying the infectious elements of contagious diseases, and a trial in private houses after scarlet fever or measles, and in hospitals after erysipelas or pyemia, gave most satisfactory results. Since adopting this method he has never seen a second case of contagious disease which could be attributed to infection remaining in the room in which the patient had been confined. The mode of procedure is very simple. From one and one-half to two ounces of corrosive sublimate are put on a plate over a chafing-dish, and then the windows and door of the room are closed. At the expiration of three or four hours the windows and doors are opened and the apartment is thoroughly aired. The person entering the room should take the precaution to hold a sponge or cloth over the mouth or nose in order not to inhale the vapor. The following day the windows are again closed and some sulphur is burned in order to neutralize any of the mercurial fumes which may linger about the furniture and other articles. The room should then again be aired and cleaned, when it will be ready for occupancy.

Slaughter-House Ordinances in Early England.—In Richard II.'s time we find an act for "the punishment of them which cause corruption near a city or great town to corrupt the air" (12 Rich. II., C. 13, A. D. 1388), the preamble of which notes that so much filth "be cast and put in ditches and other waters and also within many other places . . . that the air is greatly corrupt and infect and many maladies and diseases do daily happen." A century later we find an act under the heading "Butchers shall kill no beasts within any walled town or Cambridge" (4 Henry VII., C. 3, A. D. 1487). The preamble of this speaks of the "Corruptions engendered by reason of the slaughter of beasts and the scalding of swine," the "unclean and corrupt and putrified waters," and adds "that in few noble cities and towns, or none within Christendom, the common slaughter-house of beasts should be kept within the walls of the same, lest it might engender sickness unto the destruction of the people." It was nearly four hundred years later when the 317 slaughter-houses scattered promiscuously in New York City below Eightieth street, were driven out and the work concentrated in clean abattoirs outside. When London was to be rebuilt after the great fire, a law was passed for "the cleansing and scouring of vaults, sinks and common sewers" (19 Ch. II., C. 3, A. D. 1667), and in 1670 another was passed for the better paving and cleansing of the sewers and streets in and about the city of London.

Hospital for Consumptives at Paris.—A part of the large estate of the late Madame Boucicault will be directed to the establishment of a hospital for the treatment of tuberculosis. The hospital is only one of the many objects of charity for which Mme. Boucicault left money, but it is the most important. The buildings have cost with furniture, about $650,000 and a sum of $1,500,000 was left for its maintenace, the interest of which will amount to about $45,000 a year. Any expense not covered by the gift will be liquidated by the Assistance Publique, which, besides receiving money from the city, receives yearly large bequests from private charity. This institution which bears her name, is upon the point of opening, in the charge of Professor Maurice Letulle, who has had marked success in his treatment of tuberculosis at St. Antoine. The new hospital has an ideal situation in the comparatively open quarter of Paris known as Javel, which is on the south side of the Seine opposite Auteuil. The building is isolated, even the four streets inclosing it being wide and little traveled. Although the building is large there will be but 160 beds, as the great object is plenty of space and ventilation. Of these beds only thirty-two will be devoted to consumptives at the beginning, but it is believed that the hospital will eventually become one for such cases only, and the buildings have been planned with that end in view. Sixteen beds are reserved for employes of the Bon Marché; otherwise the hospital will be absolutely free. The main improvements to be noted are in the condition relative to the housing of the consumptive patients. The two wards to be devoted to them exclusively from the start occupy separate pavilions. The wards themselves are glass-roofed galleries, the sides of which may be made entirely open. This is for the air treatment, which is a method constantly growing in favor. The patients will, practically, eat, sleep and live out of-doors, without draughts and protected by the glass roof. Only in stormy and very cold weather will the galleries be closed. The flooring is of polished hard wood, the furniture of enameled iron, and there is no curtain or drapery of any kind. The object is to be able to disinfect the entire apartment by means of steam and hot water. The mattresses are made of wood fiber, sterilized and uninflammable, and the system of spittoons is entirely new. The matter of instant sterilization of all discharges from the patients' mouths and throats is to be carefully looked after. Finally, the clothing of patients, nurses and servants is to be specially fashioned, and is to be kept constantly disinfected. The patients, also, are to be graded as to the stage of the disease in which they may be. Incurable patients are to be isolated in smaller rooms away from the wards.

ASSOCIATION NEWS.

Section on Laryngology and Otology.—A bound reprint or volume of the Transactions of the Section on Laryngology and Otology at Philadelphia will be prepared; after publication in the JOURNAL and furnished to subscribers at $1 per volume, provided seventy-five subscribers can be at once received. Those wishing the volume and who have not already entered, therefore, will please send their names without delay to Dr. W. E. CASSELBERRY, Chairman, 34 Washington Street, Chicago. It is urged that as many subscribe as possible as the valuable papers contributed at this meeting will thus be preserved in book form, and the custom of issuing an annual volume established.

BOOK NOTICES.

The Physician's Visiting List for 1898. Leather. Philadelphia: P. Blakiston, Son & Co. Seventy-five cents to $1.25.

This visiting list contains calendars for 1898 and 1899. The metric system of weights and measures, a dose table giving both the English and metric systems to correspond with the U. S. P., a table for converting apothecaries weights and measures into grams, and other data. The list is published in three styles, all containing special memoranda pages.

Transactions of the Medical and Chirurgical Faculty of the State of Maryland. Paper, 90 pages. Baltimore. 1897.

This volume of transactions covers the ninety ninth annual session held at Baltimore, April, 1897, and the semi-annual session held at Hagerstown, Md., November, 1896. The contents comprise reports of various boards, committees, etc., lists of presidents, vice-presidents and members, the presidential address on "The Functions of a State Faculty," by Wm. Osler, M.D., and the annual address, "Does Medicine Advance?" by David W. Cheever, M.D.

Transactions of the South Carolina Medical Association. Paper 129 pages. Walker Evans and Cogswell Co. Charleston, S.C.; 1897.

This volume contains the transactions of the forty-seventh annual meeting, held in Union, S. C., April 28 and 29, 1897. The following papers appear: Ectopic Gestation; Observations on Continued Fever; Carbolic Acid in the Treatment of Hemorrhoids; Graves' Disease; Oxygen Gas as a Local Therapeutic Agent; Remarks on Otitis Media and Otitic Syphilis; Up-to Date Treatment of Cataract; Kangaroo Tendon as a Ligature and Suture in Ovariotomy; Dr. Paquin's Antitubercle Serum; Removal of Pus Tubes and Appendix; Acute Opium Poisoning; Trephining for Traumatic Epilepsy; Leucocytosis on Element in Diagnosis and Prognosis.

Transactions of the American Surgical Association. Vol. xv. Edited by DEFOREST WILLARD, A.M., M.D., PH.D. Printed for the Association. Philadelphia: William J. Dornan. 1897.

This volume contains the usual number of interesting papers by members of the Association, and necrology reports on Sir Thomas Spencer Wells, Sir John Eric Erichsen, Sir George Humphry, William Hunt, William H. Pancoast, Perry H. Millard and J. Edwin Michael. The addresses and ceremonies on the occasion of the presentation and unveiling of the Gross statue are given, an excellent half-tone showing the statue itself with the Army Medical Library in the background. Altogether one of the most notable volumes of this series yet published, especially from a historic point of view.

The Journal has heretofore published an account of the meeting (see Journal, May 15, 1897, p. 947), and commented at length upon the character of this session.

An abstract of the papers can be found in the Journal, May 29, 1897, page 1025.

MISCELLANY.

Errata.—In "Some Practical Points on Infant Feeding and Infant Feces," *vide* Journal, December 11, page 1197, at the end of Formulas 2, 3 and 4, the amount of milk sugar should read 6¾ drams instead of 6¾ ounces.

The Pasteur Prize offered by the "Circulo Med. Argentino." was awarded to Dr. José Sanarelli, for a communication describing his experimental work in the line of immunization against yellow fever. As his article was the only one received, Dr. Sanarelli refused to accept the prize.

The Necessity of Aseptic Cushions for the operating table is urged by P. Klemm of Riga, who recommends for the purpose bags made of stout linen, of the required shape, filled as needed with excelsior (Holzwolle), and sterilized with steam, or the bag and excelsior can be sterilized separately. He has found these cushions convenient, cheap, absolutely aseptic and superior to rubber cushions for several reasons.—*Cbl. f. Chir.*, November 16.

Hay-fever at Carlsbad.—M. Müller reports in the *Wien. Klin. Rundschau* of October 31, his opportunity to observe several cases of hay-fever among Americans at Carlsbad. After describing in detail the familiar symptoms, he mentions that he succeeded in abating them to such an entent that the patients were enabled to return home and not wait for frost as usual. His treatment was a full course of the waters and local applications of a 20 to 30 per cent. solution of argentum nitric., with which he touched the nasal mucosa, following it with a spray of Carlsbad water.

Dystrophia Muscularis Progressiva.—A case was recently observed by E. Bonardi, described in the *Gaz. d. O. e d. C.* of August 15, that combined the more common picture of facio-scapulo-humeral dystrophia of Dejerine Landouzy with the rarer Brossard femoral dystrophia with pes equinus, etc. Both affections were typical manifestations, non-symmetric, with a functional lesion of the left eye, like a mist constantly before it, which the specialist was unable the remove. The first symptoms appeared at 19, with weakness of the limbs and inability to step on the heel.

The Conductibility of the Nerves in Both Directions is not demonstrated by physiology, but pathology and therapeutics confirm it in many ways, especially by the phenomena of electricity, catalepsy and suggestion. . . . The production and cure of morbid conditions by psychic stimulation appear in an entirely new aspect when viewed by the light of double nerve conductibility. . . . The fact is too often forgotten that the excitations originating in diseased conditions of the nervous system are usually propagated according to entirely different laws and in different directions from the physiologic stimuli. To correct the false deductions we have made in this respect, will be the task of the next generation. . . . Orschanski states that the nervous system is constantly in a condition of activity, which he calls nerve tonus, in its efforts to maintain the temperature and the general economy of the organism. It is probable that this tonus requires centripetal stimulation of the motor nerves and centrifugal of the sensory.—From Prof. M. Benedikt's address in the Phys. Section at Moscow. *Deutsche Med. Woch.*, October. 7.

Spontaneous Sediment; Formation in the Blood a Method of Scientific and Clinical Investigation.—E. Biernacki has established the fact that the sedimentation of the blood is by no means a purely mechanical process, but depends upon certain factors which render it a valuable aid in scientific and clinical investigation along different lines from the hematokrit and centrifuge. The rapidity of the sedimentation is an indication of certain alterations in the blood which no other method is able to detect. It depends upon the amount of fibrinogen in the blood and varies with it. Another fact established by it is that the fibrinogen is in direct proportion to the capacity of the blood for oxygen, and the amount of oxygen contained in it, forcing the conclusion that fibrinogen is an albuminoid involved in oxidation, and hence that the variations in the amount of fibrinogen indicated by the rapidity of sedimentation point to abnormal processes of oxidation. His numerous experiments and the standards he has adopted for comparison are given in full in the *Deutsche Med. Woch.*, of November 23.

Faure's Method of Total Abdominal Hysterectomy is described and illustrated in the *Presse Méd.* of October 19. The abdomen is opened, the surgeon at the left, and the fundus is seized with forceps each side of the median line. With a scissors it is then cut down straight on the median line into the vagina, applying forceps half way down and again to the two stumps of the cervix. Each half then shells out from below upward, like a ripe nut, held only by the utero-ovarian vessels, which are then severed after seizing with forceps. The operation is surprisingly simple and easy. The only disadvantage is the opening up of a possibly infected uterus, but the danger from this is slight and can be prevented by touching the lips of the incision with the thermocautery. It is also an easy matter to disinfect the small pelvis afterward if necessary. The method is especially adapted to suppurated adnexa, as they are removed intact and all danger of infection from this source is avoided. It also avoids approaching the lesion from the periphery, which is frequently laborious and dangerous. He considers it applicable to all uteri of normal or slightly more than normal size. Cut in two from above down, the two halves, freed from their lower attachments, roll out from the vagina upward and can be enucleated with remarkable facility.

A Medical Man Honored.—Dr. Alexander Hill has been elected to the honorable position of Vice Chancellor of Cambridge University. This is the first time in history, says the *Lancet*, that the highest executive office of one of the two leading English Universities has befallen a medical man. John Caius, who, like Dr. Hill, was a student of St. Bartholomew's Hospital, ruled over the College, which he refounded and endowed, from 1559 to 1573, but he did not fill the office of Vice Chancellor. John Harvey was appointed Warden of Merton College, Oxford, in 1644, but lost his office six months later on the fall of Charles I. Of other medical men, if any, who have filled headships of colleges there is, we believe, no record, Dr. Alexander Hill's mastership of Downing alone excepted. Of late years medicine has made great advances at the universities, and we must look upon the election of Dr. Hill not only to the mastership of Downing but to the Vice-Chancellorship of the University as a proof of the increasing influence of our profession at Cambridge, and also as one of many recent indications that medicine is rapidly stepping into a position of equality with the sister professions of theology and law. Dr. Hill holds the office of Lecturer in Advanced Anatomy to the University. He was for some time Hunterian Professor of the Royal College of Surgeons of England. He is the author of many papers on the anatomy and physiology of the nervous system, the translator of Obersteiner's "Central Nervous Organs," and the author of the "Physiologist's Note Book" and other works. Last year he succeeded Sir William Broadbent as President of the Neurological Society and it is as a neurologist that he is chiefly known to the profession.

Treatment of Putrid Abortus, Hemorrhagic Endometritis, etc.—Pincus considers steam almost a specific for these conditions. He uses a wooden speculum and injects a stream of steam at 100 degrees C. for two minutes (*Wien. klin. Rundschau*, October 10). This treatment is enthusiastically endorsed at Prague, where it is extensively applied. The technique there is described in an article in the *Presse Méd.*, of October 2. Schick prefers a boiling water, which he injects into the uterus for one minute, never more than a minute and a half. To prevent burning the vagina, he injects a constant stream of ice-water into the vagina at the same time. The uterus is first dilated and the patient put to sleep; she is also kept in bed until the eschar falls, which requires about three weeks. The wick of gauze in the vagina is changed every four or five days, and the vagina irrigated occasionally. No accidents nor inconveniences were observed at any time. In rebellious hemorrhagic endometritis, hemorrhage after curettement of uterine cancers or after abortion, and the metrorrhagia of the menopause, this treatment has proved a perfect hemostatic. In the first named, two cauterizations at an interval of a month or six weeks, have sometimes been required before the cure was complete.

Holothyrus Coccinella; a New Parasite.—M. Mégnin recently showed before the Paris Academy of Medicine a parasite of a fairly large size which had been sent to him from the Mauritius by Dr. Charmoy for the determination of its zoologic position. It is the holothyrus coccinella of Gervais. Its popular name is "trouille canard," and poultry farmers know its noxious properties so well that they have given up breeding birds in those elevated and damp regions of the island where this parasite abounds, lying hidden during the day under the moss and stones. Even children have often fallen victims when, having found a "trouille canard," they have put their fingers in their mouths after having touched it, for the tongue and pharynx become affected with an exceedingly painful swelling so that they are in danger of asphyxia. With his last consignment of these parasites M. Mégnin tried some experiments to verify the existence of these unheard-of properties. If one is applied to the skin and kept there by a bandage, a burning sensation is felt, which after a time becomes very disagreeable, although the skin is only slightly edematous and exhibits no change of color. Upon mucous membranes the effect is very much more pronounced.—London *Lancet*.

A Simple Regimen for Obese Persons.—Dr. Cathell reports that he has had more than ordinary success during several years with a plan of treatment outlined below. In his view, obesity is due to one or more of the following causes: Congenitally small lungs with a defective oxygenating capacity; eating excessively of all kinds of food; want of lung-expanding exercise; using alcoholic drinks to excess. Many of the drugs which have a known fat-reducing power exert an injurious action on the other tissues of the body, and if used persistently for any length of time, or in efficient doses become dangerous to health. While the various obesity cures are so rigorous that few carry them out conscientiously, the treatment of the author is very simple. The patient has only to drink after each meal a glass of the artificial Kissingen water to be found at drug stores and soda water fountains, and on the succeeding day, a glass of artificial Vichy water also half an hour after each meal. This is to be continued week after week until the patient comes down to a normal degree of stoutness, and the waters are then discontinued. While taking the waters the person should keep a weekly record of his weight, always using the same scales, and wearing the same clothing, and should also, for his own satisfaction, record his chest, waist and hip measurements. If the loss in weight exceeds two pounds a week, the amount of each water should be made smaller; and if the loss has not equaled two pounds a week, a few teaspoonfuls of lemon juice should be added to each glass of the Kissingen water to increase its acidity, and a teaspoonful of aromatic spirits of ammonia to the Vichy to increase its alkalinity. The diet should be light and contain only small amounts of fat, starch, sugar, and alcohol. Moderate outdoor exercise should be included in the day's program. The mode of action of these waters taken in the manner described, is not clear, but their efficiency is too well established to admit of doubt.—*Maryland Med. Jour.*

Denver.

THE DENVER AND ARAPAHOE MEDICAL SOCIETY.—At the regular meeting, December 14, Dr. S. G. Bonney reported "An Unusually Successful Result of Thyroid Treatment in a Case of Myxedema." The patient was a woman aged 54 years, whose father died of cerebral embolism, mother and one sister of cancer. Previous history was good. On July 31, 1897, the patient presented the characteristic symptoms of myxedema; features enormously swollen; nose flattened; lips bluish, the lower somewhat everted; eyelids full and distended; constant watering of the eyes; pronounced lemon discoloration of hands and neck; tongue much swollen; speech slow and hesitating; very apparent mental hebetude. Subjective symptoms: Pricking of skin, coldness of feet, frequent sharp burning sensation in extremities; skin dry, hard and fissured; hair dry and coarse; nails brittle; vision and hearing impaired. Temperature by mouth at 2 P.M. 96.4. Pulse 60, weak, compressible. Treatment was instituted, August 3, which consisted of complete rest, and a 2 grain tablet of dessicated thyroid extract, prepared by Armour & Co., two hours after breakfast. After the second dose the temperature had risen to 97.2. On the third day temperature was 97.4, with diminished lachrymation, improvement in quality of voice and for the first time in many months she began to feel the return of strength.

The improvement continued steadily, and on September 3, after one month's treatment, all the above enumerated symptoms have disappeared. She has diminished about one third in size; lost nearly thirty pounds in weight: feeling of vigor, almost buoyancy; pulse 86; temperature normal, and an apparent complete return to a normal condition has been secured. Only once during the treatment did the patient feel badly, which was attributed to the administration of an additional tablet of the thyroidin. The administration of the drug was suspended for two days and again resumed, without any further trouble. Dr. Bonney in summing up the case, made the following practical deductions: 1. The remarkably short period of treatment. 2. The brilliant results obtained from unusually small doses of the thyroid. 3. The danger attending the indiscriminate and injudicious administration of larger doses especially with the patient not under competent observation.

Dr. J. T. Eskridge, in opening the discussion, gave a short historic résumé of the treatment of the thyroid gland. He highly complimented the work of H. Gideon Wells, Ph.G., of Chicago, for his elaborate and excellent paper on the "Physiology and Therapeutics of the Thyroid Gland" which was published in the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, October 30, November 6 and 13, 1897. The treatment of cases of myxedema, he said, is divided in two stages. The first is for the relief of symptoms, and the second to maintain the degree of health secured. He usually begins with the administration of two to five grains daily. Rapid action and palpitation of the heart, slight dyspnea, pains in the legs, headache, etc., indicate that the dose should be diminished or that the agent should be discontinued for a few days. He had employed the animal extract in ten cases of obesity with failure to reduce the weight in one. In three of the nine cases thirty pounds each were lost, while the strength and general well-being of the patient seemed decidedly increased. In a number of cases he found it necessary to give strychnin and spartein to sustain the heart during the most active period of the thyroid treatment. The loss of fat is permanent. Dr. Eskridge also made a résumé of the literature on the thyroid treatment in ununited fractures (*British Medical Journal*, Sept. 12, 1897); pelvic congestion (Twelfth International Med. Congress "Gynecologie"); skin diseases (*N. Y. Med. Jour.*, Nov. 20, 1897); mental diseases (*Journal Mental Science*, January, 1895; *Dublin Jour. Med. Science*, August, 1895; "Practical Therapeutics," vol. ii, p. 292). He thinks it probable that it might be used with advantage in some of the depressive states of the nervous system, and in cases of retarded development both mental and physical. He is at present trying the treatment in a few cases of infantile cerebral palsies. Drs. Edson, Freeman and Rothwell each reported a case of myxedema in which the thyroid treatment was successful.

Dr. CHAS. DENISON read a paper entitled "Passing Consideration of the Antitoxin Treatment of Tuberculosis, Wayside Remarks on the Direct (tuberculin preparation) Versus the Indirect (animal serum) Method of Immunization Against Tuberculosis." He prefaced the paper by the following remarks: "From the absurd advertisement of a Swiss barber, 'Tuberculin injections given here,' and the [illegible]ually prep[illegible] terous belief which at first prev[illegible] at [illegible] s to d[illegible] tuberculosis has been discover[illegible] hou[illegible] remedy, we have come to [illegible] t m[illegible] by a concentration of skilled effort, and by a technique involving as much discrimination in diagnosis and care as does the differentiation of a complicated eye refraction, the microscopic determination of blood changes due to disease, the endoscopic study of internal organs or any other delicate field of professional work." He divided the tuberculin products into two classes: A. Those which are supposed to work by their toxin, creating or stimulating the production of an antitoxin in the blood of an affected person. B. When the antitoxin has already been produced in an animal's blood, preferably one already immune, and then through its serum made available in the treatment of tuberculosis.

To the first class belong: 1, the crude original tuberculin of Koch; 2, tuberculocidin, Klebs' first modification of the former; 3, antiphthisin, practically the same product as Klebs manufactured in this country; 4, tuberculinum purificatum of Dr. Karl von Ruck of Asheville; 5, purified tuberculin of Dr. Whitman of Los Angeles; 6, oxytuberculin of Dr. Hirschfelder of California; 7, Koch's new tuberculin (T. R.); and 8, Dr. Karl von Ruck's watery extract of the bodies of the dead bacilli.

To the second class belong: 1, antitubercle bacilli of Paul Paquin; 2, Professor Crandal's (St. Louis) serum; 3, the serum prepared by the H. K. Mulford Co. of Philadelphia, and the antiphthisic serum (T. R.) made by the John T. Milliken Co. of St. Louis according to the formula of Dr. Carl Fisch. This serum is peculiar in that the selected horses from which it is taken have been strongly immunized, charged with Koch's new tuberculin (T. R.), the process usually taking four months and the serum being drawn fourteen to twenty eight days after the last injection. When it is considered that for a last dose 150 c.c. are given the horse, we can get some idea of the enormous load of tuberculin these animals are carrying in their blood, by remembering that according to Koch the initial dose of tuberculin (T. R.) should be one five hundredth of a milligram. Dr. Denison gave in brief the result of the various experiments of Dr. Fisch, and the histories of seven cases which he himself treated with the last named serum. Dr. Denison has obtained good results in all his cases, and has not met with any untoward effects so frequently encountered in the use of the other tuberculin preparations.

Dr. Bane reported a case of an "Animate Body in an Ear." The patient, a woman, was exposed in a storm in Arizona and for several days the cold wind blew against the right side of her face. A day after she experienced a peculiar sensation in her right ear. The ear became very painful, swollen, tinnitus constant, with severe pain in the salivary glands upon taking liquids or doing anything that would excite the flow of saliva. On looking into the right canal he noticed a greenish substance that almost filled the membranous portion, which he easily removed. It was found to be a lively insect 4 by 6 mm. in diameter, and 2 mm. thick. It lived for two days and was identified as a wood-tick, *Ixodes*.

Louisville.

Health Office.—It has been announced that the new Board of Public Safety appointed by Mayor Weaver will remove Dr. W. P. White from the office of Health Officer and appoint as his successor Dr. M. K. Allen. Dr. White has had the endorsement of the Louisville Medico Chirugical, the Clinical, the Surgical, the Falls City Medical Society and the Practitioners' Club, besides the private endorsement of the majority of the practitioners of the city; yet in spite of this the removal of Dr. White has been decided upon. From present indications it was decided upon before the election. Dr. White has made a most excellent record as a health officer and it is a great disappointment to all that this office has been made a political gift.

Falls City Medical Society.—At the last meeting of this Society Dr. Albert Muench read a paper entitled "The Treatment of Acute Urethritis."

Report.—The seventy-third annual report of the Eastern Kentucky Asylum for the Insane has just been issued by its superintendent, Dr. Edw. M. Wiley, for the fiscal year ending Sept. 30, 1897. The Board of Commissioners in their report, embodied in it, ask for an appropriation of $10,000 for the purpose of constructing an adequate artificial sewer. This will be referred to later in speaking of the superintendent's report. An adequate hospital and a gas plant is also asked by the commissioners. Several thousand dollars will be needed for the necessary repairs to the buildings, which is not to be wondered at when it is remembered that this asylum is the oldest one west of the Allegheny mountains. It is urged by the commissioners that the appointment of the superintendent be taken from the Governor's hands and placed in the commissioners', thus removing it from politics entirely. The census at the close of the year showed 817 inmates, 1,027 being treated during the year. The place is in a most deplorable sanitary condition, with a sewerage system which overflows, damming the refuse back until it has contaminated five cisterns, the typhoid bacillus being found in two of these and sewer gas in the rest. As a result of this there have been forty-two cases between August 12 and October 31 of typhoid fever. The report goes on to say that there is no provision for examining patients or their care beyond the public wards and the rooms in which patients are confined, and as a result of this ten attendants requiring treatment during the typhoid fever epidemic had to be sent outside the building. The provision for the erection of a suitable hospital is earnestly urged. There were a total of 103 deaths during the year. As to the age of those admitted during the year it is interesting to note that thirty-four of the 236 admitted were between 20 and 25 years and thirty-five between 25 and 30 years. Fifty-eight of the females admitted were domestics. Thirty-three of the males were farmers and forty six farm laborers. The remarkable number of insane among the farming class was called attention to on a previous occasion in these columns. Consumption caused seventeen deaths and pneumonia twenty-six. The cases of pneumonia occurred at the time of the overflow of the sewer. Farm and garden products to the value of $12,827 were produced on the lands of the institution during the year.

THE PUBLIC SERVICE.

Army Changes. Official List of Changes in the Stations and duties of officers serving in the Medical Department, U. S. Army, from December 11 to 17, 1897.

Capt. Isaac P. Ware, Asst Surgeon, ordinary leave of absence granted, under orders for duty at Benicia Bks., Cal., is extended one month on account of sickness.

Major Louis Brechemin, Surgeon (Ft. Sherman, Idaho), is granted leave of absence for one month, to take effect about Dec 15 1897, with permission to apply to the Adjutant General of the Army for an extension of two months

First Lieut Guy C. M. Godfrey, Asst. Surgeon, will be relieved from duty at Ft. Sheridan, Ill., and will report in person to the commanding officer of the detachment of troops at Finn's Point, N. J., for duty at that place and at Ft. Delaware.

be implicated, is less fatal to the eye than a similar wound in the sclerotic." The hemorrhage in the former instance, is into the anterior chamber, and mixing with the aqueous humor it is rapidly absorbed; whereas in the latter, if hemorrhage ensues, it is into the vitreous, and frequently also between the choroid and retina. Blood in the vitreous is slowly absorbed, while irreparable damage is done to that portion of the retina which has been displaced by a blood clot. Wounds of the sclerotic sometimes heal with difficulty, and the difficulty increases as the location of the wound recedes from the margin of the cornea. This is probably occasioned by the fact that the margins of the wound remain patulous, the tissues of the sclerotic refusing to yield to the diminished size of the vitreous within it; hence it is that wounds in the sclerotic where only a small quantity of vitreous has escaped, there is a tendency for the lips of the wound not to come together, and a consequent inability for primary union. These wounds, however, unite quickly if the edges are brought in apposition by a fine silk suture. Dr. Bowman reported two cases illustrating this fact. "In the first patient there was a wound in the sclerotic which had remained patulous for three days, and in the second, no attempt at union had taken place one week after the accident, yet, in each case, immediate union followed after the edges had been brought into accurate apposition by a single fine suture." The occasional cystoid cicatrix, which is found, could, we think, be avoided by recourse to suturing. The danger of a wound to the eyeball is immensely increased, if the injury is located in the sclero-corneal region involving the ciliary body. The risk to the injured eye is very great, but the chief danger is the chance of the other eye becoming involved in a sympathetic ophthalmia.

Lastly, we come to consider briefly that class of wounds in which the projectile remains within the eyeball. Every penetrating wound of the globe should be especially examined with reference to the possibility of there being a foreign body within the eye. The history of the case should be carefully gone into with a view to ascertaining the exact nature of the material which struck the eye, whether large or small, by what force and in what direction it was propelled against the eye. The eye itself should be examined first superficially, then the iris and lens. If the wound in the cornea suggests the possibility that a foreign body may have penetrated it, and yet the foreign body is not visible in the iris or lens the pupil should be dilated with atropin to bring the lens into full view, because it may have lodged in the margin of the lens and behind the iris. Oblique illumination is of immeasurable value in this examination of iris and lens. If such an examination does not reveal the foreign body, and the conditions are favorable, a thorough ophthalmoscopic examination of the whole fundus should be made, and the foreign body located if possible. Unfortunately, however, these injuries are sometimes attended by hemorrhage, which entirely obstructs the view of the interior of the eye. Dr. Rohmer[4] in a very able article on "Extraction of Metallic Foreign Bodies from the Posterior Segments of the Eye by the Electró-magnet," says: "When a foreign body reaches the deeper parts of the eye, it will cause disorder varying in intensity and gravity according to its size, the region of its entrance, its degree of cleanliness, its chemical composition, the place which it occupies, and its action on the neighboring parts. After its penetration, the eye may be immediately and irrevocably lost from the extent of the lesion, escape of vitreous, hemorrhage or infection. Or the foreign body entered by a very small opening, and only caused an insignificant lesion, with partial or complete preservation of vision."

The location of a foreign body in the eyeball will in a measure determine the degree of tolerance, the different structures reacting differently to its presence. In the lens, for instance, a small foreign body may be borne well for years, and be ultimately removed with the schriveled and hardened cataract. In the posterior segments, however, a foreign body will rarely be tolerated. In the vitreous, choroid, and ciliary body, even though the foreign body became encapsulated there will sooner or later develop a plastic or purulent inflammation, with consequent destructive ophthalmitis.

The treatment of these cases will depend upon the nature of the foreign body. Coppez made the observation that in seventy cases of foreign body in the posterior hemisphere of the eye, forty-two were iron or steel, ten were lead-shot, ten fragments of cartridges or pieces of copper, six fragments of stone, one zinc, one wood.

If the foreign body is magnetizable it should be removed as soon as possible after the accident with the electro-magnet. From the statistics[5] gathered at the clinic in Zurich by Hirschberg it is apparent that during the four years preceding the use of the electro-magnet in cases of metallic fragments in the vitreous, there were twenty-four cases treated, all of which were recorded as failures, that is, 100 per cent. During four succeeding years in which the electro-magnet with antisepsis were employed, of thirty-five cases there were only twenty-four failures, that is, 68 per cent. In his own practice without the magnet he did not have one successful case, during the first ten years. In the following ten years with a magnet, of thirteen successful cases, seven were noted as satisfactory, and six as mediocre. These figures certainly justify the use of this method, and we need not discuss this proposition at greater length.

If the foreign body is not magnetizable, the eye should be enucleated as soon as there are signs of obstinate inflammation.

SURGERY ONE HUNDRED YEARS AGO.

AN HISTORICAL STUDY

BY DR. GEORGE FISCHER.

DEDICATED TO THE GERMAN SURGICAL ASSOCIATION.

TRANSLATED FOR THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION
BY CARL H. VON KLEIN, A.M., M.D.

IX.—THE ACADEMIE ROYALE DE CHIRURGIE AT PARIS.

PIERRE JOSEPH DESAULT.

(Continued from page 179.)

Medicine had from the first not kept pace with surgery in France; the latter had always been pursued with partiality, while the former had been neglected, so that, with a few exceptions, French physicians had not made brilliant records. The chief reasons for this failure of medical study were, the too brief period devoted to it, the neglect of the supplementary studies, the selling of the doctor's degree, and above all the separation of medicine from surgery. This had continued in France, as in Germany, since that unfortunate time when the Catholic church forbade the clergy to perform any operation whatever. As a result the science sank to the level of a trade. Indeed, the Italian, Lanfranchi, who in 1295 had fled to Paris, taught both sciences, practiced both, and declared that their separation was an evil; but centuries must pass before the Revolution ushered in a wholesome reform. The political equality of physicians and surgeons, and of the sciences of medicine and surgery, had been established, and must have, as a consequence, the reunion of the two sciences. Suggestions for the improvement of medicine were sent in by different societies. Chaussier showed the absurdity of the separation of medicine and surgery, and exposed the abuse, on the part of the body surgeons, of extorting money and selling appointments (1789). The Royal Society of Physicians also, in an address to the national convention, contended for the inseparability. The propositions which were made agreed with the report or instruction by Talleyrand, one of the best minds which arose out of the Revolution; but the flight and capture of the King diverted the attention of the national convention from the subject of education, and Talleyrand's plan, along with others, was pigeon-holed. The convention met. The leaders of the Reign of Terror were reproached with wishing to banish science and the arts, as they decreed the suppression of the Academy and the societies and caused the persecution and death of certain scholars. The accusation is not entirely just. They abolished those institutions and those learned societies, because they had been privileged and endowed, and now the sentiments would not allow of the existence of any privileged body. They bore upon themselves the stamp of despotism, and their organization conflicted with the principle of equality; therefore they must fall. Lavoisier must die, not because he was a great scholar, but because he had been a tax-levier. Desault's imprisonment was the result of the personal hatred of certain rogues, but his scientific deserts saved him, for he remained under arrest only three days. A physician in Arras was denounced at the instance of his colleagues, and executed because he had a picture of the King in his room. It is also to be remembered, that much of the mutilation of works of art is to be ascribed only to subalterns; Henriot, the commander of the national guard, demanded that all libraries be committed to the flames. But no systematic extirpation of the sciences took place, and even at that time, among other things, the botanical garden in Paris, was considerably enriched. Then followed the strenuous persecution of the monasteries and the clergy; a mass of old parchment-rolls, which perhaps contained valuable manuscripts, was used for cartridges. According to the crude conception of liberty and equality which the mob had, even scholars, because of their prominent position, must be opposed to it; they were treated with distrust. All the destruction wrought resulted in less injury to science than the complete diversion of all forces to the field of politics, the consternation, and the death of many talented men upon the battlefield. All this thrust science to one side. During this time Vicq d'Azyr died, bowed with grief over the horrors of the Revolution. Excepting a law for military hospitals the convention did nothing positive. After the fall of the tyrants, the need of improvement in medicine again appeared in the foreground. Till 1792, when the Revolution abolished public instruction in medicine, the separation of medicine and surgery had been rigorously maintained; when in the year 1794, at the suggestion of Chaussier and Fourcroy, the Ecoles de santé, described in a previous chapter, were founded, *medicine and surgery were again united.* Without doubt the Revolution accomplished this, instruction was essentially improved and practical clinics organized. According to the proposition of the physician and deputy Guillotin. whose name is immortalized in the executioner's ax, all academical degrees and titles should be abolished, and all practitioners should bear the name physician, which was changed in 1794 to officier de santé. In spite of many reforms, the social conditions left much to wish for. One who wished to practice must pay twenty francs a year (though advocates paid nothing), and officiers de santé were classed with furniture dealers, carriage-makers, hair-dressers and others, in the fourth tax-class.

Let us return to the French surgeons. In the first half of the eighteenth century, the scepter of surgery was held by *Jean Louis Petit* (1674–1750), before whom all contemporaries must bow. Even as a boy he studied anatomy under Littre, who lived in the house of his parents, and in his 12th year he began the preparation of those lectures which he afterward delivered to his students. Later he studied surgery under Maréchal, and in 1692 became military surgeon in the French army in Flanders, where he was charged with the supervision of a hospital in Tournay. After his retirement from the army (1700), he went to Paris, became master of surgery and began to give anatomic and surgical lectures. Some years after (1705), appeared the work on diseases of the bones (chiefly fractures and dislocations), upon which the young Petit laid the foundation of his later fame. This work, of which Boerhaave said "tractatus hic nunquum sibi parem habuit," was for half a century the best of its kind. Petit wrested the treatment of fractures out of the charlatanism of the bone-setters (bailleurs), and instead of straining after theories and hypotheses in the manner of his time, he gave his experiences and operations. It had hitherto been a general misfortune that only those who had no surgical practice were writers, while the practitioners seldom published their notes. The Paris Academy of Sciences and the Royal Society of London admitted Petit as a member, although according to the standards of that time he was no scholar. His reputation soon became so great, that the kings of Poland and of Spain invited him to their kingdoms and made him very flattering proposals, which, however, he declined. He worked many yaars on his celebrated "Traité des Maladies Chirurgicales," which, in three parts, only appeared after his death (1774), and contained a rich experience and a mass of new ideas. Petit wrote little, but his works were classics (mostly in the "Mémoires de l'Académie), and there was no lack of venomous critiques against him. We have him to thank for the invention of the screw tourniquet, by which operations on the extremities became less dangerous; for the circular amputation: the operation for strangulated hernia without opening the hernial sacs, besides many improvements upon methods of operating. He was an eminent operator. *Le Dran*, one of the best of surgeons, officiated with him in the Charité. With clear comprehension and sound judgment he combined an easily understood diction, and distinguished himself above many of his countrymen for a simple, fundamental exposition. Especially celebrated as a lithotomist, and as one of the first to perform the exartic. humeri, his works ("Obs. de Chir.," 2 Th., 1731), which offered improvements upon many methods of operating, were received by all nations with great applause; Cheselden, indeed, translated his "Traité des Operat." (1742). His works on abdominal wounds and gunshot wounds are good. *Morand*, who was first appointed to the Charité and afterward to the Invalides, owed his scientific education and rich experience to a firmness of purpose and great ambition, and his acquirements made him unsympathetic toward many of his vain colleagues, with their useless inventions of instruments. Never properly appreciated by his country, he declared that he was persecuted by his own countrymen as well as by foreigners (Sharp). Bitterly prejudiced against the Académie de Chirurgie for that reason, he withdrew from it entirely; so La Martinière and Louis could hardly succeed in giving him the position of body surgeon, which involved his assuming the duties of the secretary of the academy. He was appreciated in Germany; E. Platner translated his works and Richter said, in 1776, that a La Peyronie, Le Dran or Morand must soon arise, if the glory of the Académie de Chirurgie was not to fall. Morand endeavored to make surgery as simple as possible, and to spare operations ("Opusc. de Chir.," 2 Bde., 1768–72). He attained a reputation by the introduction into France of the side incision for lithotomy, after he had been sent to London by the Royal Society for the purpose of learning Cheselden's method. With him began the history of exarticulatio femoris, based upon experiments upon animals which he had two of his students make. He also recommended extirpation of the ovaries. In a demonstration of Bilguer's work on amputations, Morand showed himself as having a better mind and a far higher education than his German opponent. In *Garengeot* much energy and mechanical ability were combined with some insolence, in that, in adopting the new methods of other surgeons, he suppressed the names of the discoverers, and ignored their claims. He was demonstrator in the surgical school, and in later years was military physician, and as such was very active in the Seven Years War. Besides anatomic works, he wrote on operations (2 Vols., 1720), and instruments (2 Vols., 1723), works which contained many improvements and were very popular at that time. The invention of the dental forceps is ascribed to him. Even his own countrymen considered him a braggart. *Quesnay* was more celebrated as a national economist than a physician. Appointed by La Peyronie as secrétaire perpétuel to the academy and as professor in the Ecole de Chirurgie, he became body physician to Louis XV., who esteemed him highly, and ennobled him. Frequent attacks of the gout prevented him from employing himself in practical surgery. He wrote of suppuration, gangrene (so-called white gangrene), injuries of the head and trepannation. Imbued with a love of agriculture from his youth up, he advocated, in many political essays, the principle that the prosperity of the state depended on agriculture, and not on the mercantile and manufacturing system. Of almost the same age as Quesnay was *Arnaud* de Ronsil, who in Paris specialized on hernia, and was able to accumulate a mass of material, as the monastic nurses of the St. Lazarus were directed to send to him every patient suffering with strangulated hernia. His monograph on hernia marked a new epoch. He was the first to accurately make known the symptoms and to tell how strangulated hernia was to be distinguished from adherent hernia, to treat herniotomy thoroughly, to describe hernia obturatoria and ischiadica, and to indicate the course of the art. obturat.; for the enlargement of the lig. Poup. he suggested the use of the blunt hook named from him, instead of an incision; and for fear of injuring the art. epigastrica in an operation for crural rupture he entirely avoided the scarification of the abdominal ring. He was demonstrator of bone-diseases in the Ecole de St. Côme, but because of certain unpleasantnesses he went to London in 1746, where he practiced for thirty years. Besides the vain *De La Motte* and the eminent operator *De La Faye*, in Paris, there were in the provinces a few noted surgeons. *Le Cat*, in Rouen, was first a priest, then an architect, and finally a surgeon. As an able operator in lithotomy he became involved in a quarrel with Frère Côme, whose method he entirely discarded. *Le Vacher*, in Besançon, a son-in-law of Morand, was also known through his side incisions. In case of cancer of the breast he recommended an operation as the only remedy. *Verdier*, to whom J. L. Petit committed the management of his anatomic theater, was an anatomist rather than a surgeon. He showed that the bladder as well as the ovaries could be contained in the hernial bag. *Anel* was renowned as an oculist in the first half of the century; he wrote on hydrops of the lachrymal glands, and on lachrymal fistula ("de fist. lacr.," 1713), for which he recommended probing and injections with his syringe; he died in Turin in 1730. Then *St. Yves* and *Francois Poufour du Petit*, who measured the diameter of the eye, discovered a new method of depression of cataract, and already in 1727 undertook the extraction of cataract. The dispute over the nature of cataract, which had hitherto been regarded as a film over the lens, attracted Antoine Maître-Jean and Brisseau, who demonstrated on a cadaver that cataract had its seat in the lens.

In the middle of the century lived *Antoine Louis*, a man who in science combined high aspirations and a tireless activity with a comprehensive knowledge of the history and literature of surgery and of medical jurisprudence. His services were more considerable as a teacher and writer than as a practitioner; he advanced surgery itself but little. In place of the tourniquet, he introduced into practice generally indirect digital compression in hemorrhages after amputation, although this was not now first employed, as I have shown in giving the view of Malgaigne and Lister. As one of the first who argued, in Latin, in behalf of the admittance of surgeons into the College, he took a vigorous part in the strife between the faculty and the College. With his passionate temperament, he became involved in quarrels with the monks in the Charité, left it, campaigned a little, and then undertook the presidency of the College St. Côme. After Morand's departure in 1764, he became secretary of the academy, and as such was extremely active. The younger surgeons demanded that the memoirs should not be confined to résumés, and attacked him sharply because of his opposition, and especially Valentin with much bitterness reproached him, asserting that he did not understand the first elements of surgery, knew no Latin, and reproaching him with his experience with a case of harelip in which he had recommended an English plaster instead of the suture: this silenced him. His great vanity would acknowledge no equal, and his zeal for the academy now cooled to such extent that he discontinued the memoirs, gradually retired, and for the last eighteen years of his life was inactive. The University of Halle had conferred upon him—already a Doctor of Laws and an advocate in parliament—the degree of Doctor of Surgery, and the Academy of Vienna elected him to membership. Aside from his already mentioned work in the memoirs, which was for the most part very prolix, he devoted himself to simplifying instruments, allayed the fears of the public on the subject of being buried alive, and sought to rescue syphilitic cases from the hands of the quacks. Out of the nursery of a poor tailor, *Antoine Petit* raised himself to a professorship. He described two round anterior ligaments which extend from the uterus to the os sacrum, recommended injections through the nose by means of a bent tube for obstruction of the tuba Eustachii, and demonstrated upon a cadaver that the circulation in the thigh is not entirely stopped by ligature of the art. cruralis. The medical school in Paris owed to his generosity two new professorships which he endowed richly; he also founded, with his own funds, a hospital in Fontenai-aux-Roses, and provided for four physicians of the poor in the city of Orléans. *Sue* followed Louis as surgeon in the Charité; he held this position twenty-five years, and was also successor to his teacher Verdier, as professor of anatomy. His works on bandages and elements met with approval. The professor of surgery and inspector of the military hospital, *Hevin*, wrote a detailed work on foreign bodies in the esophagus, through which he saved Verduc's esophagotomy from oblivion; he also wrote on gastrotomy, which he repudiated, and on nephrotomy. *Le Blanc*, in Orléans, published a popular work on operations in which he repeated Le Dran and Louis. In Lyons, *Pouteau*, with his great partiality for moxas, was most prominent. These remedies had been entirely displaced by the hot iron method, but in 1760 he rescued them from oblivion and reintroduced them; he prepared them, as the Egyptians did, out of cotton, and recommended their use in severe rheumatic pains, dropsy, Pott's hump, tuberculosis, etc. He first made known Fleurant's method of opening the bladder through the rectum by means of a curved trocar, and described a method of lithotomy ("Mélanges de chir. and Oeuvres posthumes," published by Colombier). Together with a colleague, he offered a prize of 50 louis d'or for the best work on the nature of cancer poison. Another excellent surgeon was *David*, in Rouen, who in the same year as Pott, described the hitherto unknown caries of the spinal column ("Sur les effets du mouvement et du repos dans les maladies chir.," Paris, 1779). He furnished the first accurate description of necrosis (1782), as well as observations on psoas abscess. Lead preparations, and especially subacetate of lead, were introduced by *Goulard*, in Montpellier, into the treatment of various diseases. *Frère Côme* was known in Paris as a skilful, disinterested, though somewhat crude surgeon. He entered the Hôtel Dieu, then the monastery of the Feuillans, but without renouncing his profession. His methods by means of the lithotome caché (1751) involved him in many quarrels. Further, he contrived a bent trocar for opening the bladder over the symphysis pubis, and the caustic from arsenic, which is named from him. The celebrated obstetrician *Levret* surpassed all his predecessors in this science, and did good service as a surgeon in devising a twisted band for the treatment of polypus in the nose, and in the uterus.

We now come to the close of the eighteenth century. The German and French surgeons had one thing in common in that two of their number far surpassed the rest, and that both lived in the beginning and at the close of the century. Yet there was the greatest difference that the two German surgeons, Heister and Richter had indeed acknowledged gifts, while the French surgeons, J. L. Petit and Pierre Joseph Desault were great surgeons in the true sense of the word, for they possessed genius and experience, two qualities which must necessarily be combined. In spite of the great advancement which French surgery had made in the course of the century, at its close there still existed many needs and many mistaken ideas. There prevailed an unclassified mass of local remedies, which the surgeons modified and multiplied at their own will. There was an abundance of professional skill in the treatment of fractures, but on the other hand, the knowledge of their pathologic significance was slight. Almost daily a mass of instruments and operations were invented and modified. In wounds the tampon was greatly abused, in hemorrhages the bandaging was bad and they were compressed in a still worse manner. An extravagant use of trepanning was made. In the operation for harelip they strove too much after simplicity, at the expense of safety. The operations for rectal fistula were overdone, and the treatment of diseases of the urinal ducts was still in its infancy.

Now appeared *Desault* (1744–1795). As a poor village boy, he was instructed by the Jesuits in the ancient languages and mathematics; he made great progress in the latter and in order to maintain himself honorably he gave instruction in geometry. His father destined him for the priesthood, but in vain; he applied himself to surgery, but from his first teacher he was able to learn only shaving and bleeding. At the school in Béfort, anatomy was his favorite study. After five years he went to Paris, where, at that time Louis, Morand and Sabatier shone as surgeons; Verdier and A. Petit as anatomists. "To learn was his first requisite; to know, his first sweet pleasure; to surpass the others, his first passion." After a six months' illness, in consequence of great exertions in the anatomic amphitheater, in 1766 (the same year in which A. G. Richter began to teach) he offered, for the first time, private lectures in anatomy. At first, he encountered endless obstacles. The professors became resentful when their lectures began to be deserted, and those of Desault (who had scarcely left school) to be crowded; envy and fear of being eclipsed by the rising star excited them. Louis, who had persuaded him to adopt the profession of teaching, attended his lectures a great deal in order to give them prestige through his own reputation At that time, instruction in anatomy, in the detail of its descriptions, was still very inaccessible. Desault brought to its study a greater accuracy and system, and while he adapted it to the needs of the surgeon, *he created surgical anatomy in France.* In a few years public opinion regarded him among the greatest anatomists. He was not compared to the celebrated surgeons; jealousy sought, by the exaggeration of his fame as an anatomist, to overshadow his reputation as a surgeon. His career as a surgeon began with lectures on operations, and by his accurate descriptions Desault attracted a large number of students. He invented a new bandage for fracture of the clavicle, the regular setting of which had for centuries, been thought impossible, but the test of it, for lack of practice, had to be left to others, and was successfully made in the Salpetrière. For amputations he recommended the straight knife instead of the curved, an improvement which was recognized in the Hospital Bicêtre. He introduced again the direct ligature of the arteries, which seems to have been forgotten in France since Paré; it was first employed in amputations at Bicêtre. Louis, curious to see the result, feared the cords would be removed too soon, but after four days they had to be cut in order that the healing should not be retarded. These discoveries laid the foundation of Desault's fame in surgery, which now gained for him a professorship in the Ecole pratique, although, because of his poverty he was not a member of the Collège de Chirurgie. In spite of much secret opposition they made an exception and elected him to that body (1776). This gave occasion for his "Dissertation on the Extraction of Bladder Stones," a work marked by accuracy and conciseness. In 1779, he, with his friend Chopart, published the "Traité des maladies chirurgicales et des opérations," but later he would not acknowledge this work, which contained much that was old, incomplete and confused, so he had as many copies as possible bought and burned. In 1782, he became first surgeon in the Charité, and there prepared a cabinet of anatomic specimens. Three years later he removed to the Hôtel Dieu, where we have already become acquainted with him as a teacher. During his great activity in the hospital, Desault began to fill the gaps in surgical pathology. Disgusted with the superfluities in the system of surgical remedies, he limited their number. Bold in undertaking and persistent in carrying out his designs, he transformed almost every branch of the science of operations, returning to the utmost possible simplicity in methods of operating. He accurately described luxation of the radius, and devised a bandage for the little-known fracture of the olecranon, by which the bending of the forearm would be prevented. He adapted this to the analogous fracture of the patella. He also contrived a new bandage for the upper-thigh. He made the bandaging of Theden in case of varicose ulcers universal, and recommended the use of the tent in case of scirrhous tumors of the rectum. He rescued many methods from oblivion such as the continuous extension in fractures, the ligature in case of umbilical hernia, the gorgeret of Marchettis in case of fistula of the rectum, and so forth. With diseases of the urinal passage he considered the puncturing of the bladder as a superfluous method. He was the first to show the great value of the flexible sound, which could serve at the same time as a conductor of food into the stomach, and to remove foreign bodies in the esophagus. The ligature for throat polyps, was simplified, the kiotome and an instrument for the extraction of foreign bodies from the bladder, by which lithotomy could be avoided, were invented. Desault attached his name to an operation for aneurysm and introduced into France the ligature of the artery above it, and suggested in certain cases a ligature under the sack. An amputation was, to him, only a last resort. He was the first in France to show the unsafe nature of the results of trepanning, the use of which must be limited; he showed also the advantages of tartarus emeticus in cases of concussion of the brain, etc. As an operator he was bold, skilful and simple, and sought to introduce good instruments to general use, discarding what were superfluous.

The many innovations through which he, a model of correctness in observation, gave to surgery a greater simplicity, almost entirely changed the form of the science; on this account the difference between the surgery of the books of his time and that of his lectures is extraordinarily great. Desault's practical mind widely extended the limits of his profession, and there began with him, as the founder of the surgico-clinical method of instruction a new epoch in French surgery, which was based chiefly upon anatomy and physiology.

Hitherto his teachings had become known only through his numerous students, and in being disseminated from mouth to mouth had frequently reached the world in a mutilated condition. In 1791, therefore, he began to publish a *Journal de Chirurgie*, with reports of his clinics (4 Vols.), according to Richter's opinion the most important contribution which had been made to surgery for a long time. In the latter years of his life, in order to fill in the gaps in this work, Desault chose as an assistant his favorite pupil, Bichat, whom he took into his house and to whom he dictated his ideas. (J. L. Petit had worked in a like capacity.) In this way the "Surgical Inheritance," published by Bichat (3 Vols., 1795) was written.

Desault was for a long time a member of the Académie de Chirurgie, but turned away from it, as the taste for medical association was lacking in him. Slow in thought and at times difficult of perception, he had no love of those empty hap-hazard disputes, and found no enjoyment in work of which the graceful style was the best part.

When the storm of the Revolution broke out he was almost the only one who continued to give surgical instruction; in spite of his faithful work in the Conseil de Santé for the regulation of the medical service he did not escape proscription. Not a day passed without new denunciations, until finally his implacable enemy, Chaumette, the president of the Commune, twice had complaint made against him on the ground that he had refused his services to the wounded. The Committee of the Revolution issued a warrant for his arrest (1793); he was arrested in the middle of a lecture in the Hôtel Dieu and according to the report of his persecutor was incarcerated in the prison of Luxemburg "for the honor of mankind." Numerous appeals from patients and students poured in, so that after three days they were compelled to liberate him. He resumed his lectures. In the following year he was chosen professor in the newly established Ecole de Santé, for which, however, he had no sympathy. The political disquiet, the fear of new proscriptions, the death of certain friends in battle and on the scaffold shocked him deeply; from this time on he became feeble. Suddenly he was stricken with a violent nervous fever. His pupils streamed in to take care of him; Chopart and Corvisart treated him. He was delirious from the first and died on the fourth day. The people said he was poisoned, because he died a few days after the death of Louis XVI., whom he had treated in the Temple; they said he fell as a sacrifice to his steadfast denial concerning any criminal intentions on the life of that child, and other similar stories.[1]

---

[1] The commissair of the Temple, Breuillard, asked him: "C'est un enfant perdu, n'est ce pas?" The answer was: "Je le crains, mais il y a peutêtre dans le monde des gens qui l'espèrent."

The Moniteur for June 4, 1895, says: "La France l'Europe entière vient de perdre le citoyen Desault, officier de santé en chief de l'Hospice de l'humanité, le premier dans la pratique comme dans l'enseignement de l'art, qu'il a professé. Son nom est depuis longtemps célèbre dans tous les pays du monde ou la chirurgie est en honneur. son nom ne périra point. Son pays lui doit d'immenses travaux et de nombreux

According to Bichat's account, Desault was a man of middle stature, strongly built. Sharp features, small eyes, a full forehead and round face gave his physiognomy a certain severe, though not forbidding, expression. His step was vigorous, his carriage noble, his gesticulation animated, his voice strong, his speech at times difficult, as if his lips did not always find the right expression for his feeling. His diction was seldom elegant but always expressive. He knew no other pleasure than to study and to teach. He early won the confidence of the public, but for a long time neglected it, in so much that, according to his own confession, up to the age of 32 he had not earned six livres in his practice. His rare zeal led him to sleep in the hospital, that he might be always at hand, although he was not compelled to do so. In spite of his noble and generous soul, which loathed all the machinations of intrigue, his spirited and passionate character often carried him too far, so that the students did not always enjoy gentleness on his part; yet he was easily calmed again. A thirst for fame possessed him; with this and with his aspirations for surgery he imbued all his students. Desault had many friends, whom he gladly met; yet jealousy also provoked enemies, whose aspersions he met with silence and contempt. There have been few surgeons who wrote so little and yet whose fame extended so widely. He was surrounded by the most favorable circumstances for developing talents and every year the enthusiasm of 400 students proclaimed his discoveries. His teachings spread through the surgical world with great rapidity. Bichat said that Desault had found his own peculiar way of observation and had little learning; his genius alone, with which science had little to do, was the source of his services. His judgment, in this case, as in the case of A. G. Richter, was at fault. Desault was certainly not learned in Latin flourishes and quotations which passed for learning at that time. Bichat himself admitted this when he denominated as superfluous that sort of surgical learning which moved a hundred learned pens to write that which fifty writers before them had borrowed from twenty others, who in turn had copied. Desault knew the writings of his countrymen and also of the English and Germans, wherein he distinguished himself above most Frenchmen. He understood how to make use of foreign material and with this kind of learning contributed materially to science. Medicine appeared to him as a dark labyrinth, in which men wandered at random. He also thought that it was not possible to practice both professions at the same time to advantage, and, fed by partisan spirit, was fixed in his opinion against obstetrics and even against medical assistance in surgery. His enemies are fond of quoting an assertion which has been ascribed to him, that surgery must be reduced almost entirely to the knife and that six months were sufficient to educate a good surgeon. Desault was a genius created for surgery, and left his mark on everything he touched. They were able to say of him that if surgery had not existed it would have owed its origin to him.

His teacher was *Sabatier*, at first an anatomist, afterward Morand's successor in the Invalides and professor of operative surgery in the Ecole de Santé. Napoleon appointed him a member of the National Institute and also consulting surgeon. To his quiet but tireless progress surgery owed many improvements. Among many writings the most important, aside from an anatomy, is his "Médecine Opératoire" (3 Vols., 1796); clear and exhaustive, written possibly with too little critical spirit, it excelled the earlier handbooks. *Chopart*, sick and old before his time, wrote a long work on diseases of the urinary organs and introduced a partial amputation of the foot. When his truest friend, Desault, became seriously ill he did not leave him for a moment. They said that grief, possibly combined with an injury which he had suffered to his foot, contributed largely to his sickness immediately following; he died a few days after Desault. *Lassus*, in Paris, was very learned; he was a good teacher but made few original observations. The works of *Deschamps* contained nothing new; his eight-volume works on lithotomy was only of historic value. Desault's successor, *Pelletan*, whose activity in hospital work we have already mentioned, in his "Clinique Chirurg." (3 Vols., 1810) described many interesting cases, and among them was the first accurate description of fatty hernias. We will return later to the French military surgeons.

At the end of the eighteenth century, there opened a new epoch in French medicine, as well as in surgery. The herald of it was one of the deepest thinkers and finest observers, which the history of medicine presents—*Xavier Bichat* (1771–1802). He died at the age of 31, the creator of a new science, histology, and should be placed at the side of men like Aristotle, Bacon and Descartes, whose works, just as his own, mark an epoch in the history of human thought. His mind, richly equipped with the positive knowledge gained in Desault's school, had no less an object than, by an accurate study of the human organism, to tear down the structure of the old medical science and build up a new one. He perceived that the experiment which Cuvier had introduced to that end, did not suffice, and so he began to examine the tissues. Two years before his death, his "Traité des membranes en général et des membranes en particulier" appeared, and in 1801, his celebrated "Anatomie générale," in which it was shown that the whole human body consisted of twenty-one different simple tissues. He had examined each of these in its changes through differences in humidity, atmosphere, temperature, in different periods of life and in disease, in order to determine the normal and pathologic development. He realized that these investigations must in time come to be of the highest importance to pathology, and that medical observations were of no avail, if one did not know the seat of the disease. In another, just as celebrated work, "Recherches physiologiques sur la vie et la mort," he distinguished the various systems of which the organism is made up: the ganglion from the cerebral system, the organic from animal life. Bichat's doctrines had the greatest influence in the medical science of our century, and were received with the greatest applause throughout Europe. Too early, he became a sacrifice to his science; a restless activity in anatomic and surgical lectures, and in the anatomic amphitheater (in a sin-

Et trop peu pour l'humanité

gle winter he conducted 600 dissections, which kept him day and night in the atmosphere of cadavers) planted the germs of sickness; yet, when dying, he regretted that he could not complete his work. Corvisart could justly maintain to Napoleon, that no one had accomplished so much that was useful, in so short a time. In him an amiable reservation was united with strong passion; he counted fame as the food of his talent, and the hope of gaining it was the stimulus for all his work. Along with Bichat, Pinel and Corvisart in Paris, made themselves especially prominent in French medicine, in that they first insisted on the importance of objective phenomena and considered the anatomical element before all others. *Pinel* again brought forward the observation of nature, in his "Nosographie Philosophique" (1798) which was based upon the principles of Hippocrates. According to him, sickness was an abnormal variation of the various organic tissues; one must therefore consider the symptoms as external indications of disease, along with the variations of the organs, examine the seat of the disease, and only draw conclusion after a mass of phenomena had been observed. While supporting the old principles of the earlier school he gave French medicine the form of a physical science, and as an enemy of all manias for medical systems fought with the best results the Brown swindle in France. *Corvisart* recommended in his medical clinic the new medico-diagnostic method, and especially recommended the observation of the physical symptoms. To this end he rescued from oblivion the percussion method of Auenbrugger, and improved it (1808).

(To be continued.)

SOCIETY PROCEEDINGS.

The Mitchell District Medical Society of Indiana.

Proceedings of the Annual Meeting held at West Baden Springs, Indiana, June 8 and 9, 1897.

REPORTED FOR THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION EXCLUSIVELY.

FIRST DAY—MORNING SESSION.

The Society assembled at 9 A.M., and after hearing the reports of the officers and standing committees, adjourned to 2 P.M.

FIRST DAY—AFTERNOON SESSION.

The Society met promptly at 2 o'clock, with the Vice-President, Dr. J. GARLAND SHERRILL in the Chair.

The first paper presented by ADOLPH O. PFINGST, M.D., on

BLENNORRHEA NEONATORUM.

Until 1806 this disease was supposed to be due to scrofula, exposure of the eyes to the bright light, to cold, etc. Its relation to vaginal and urethral diseases was first pointed out by Schmidt in 1806. The true nature of the infecting material, however, was first made known in 1879, when Neisser demonstrated the gonococcus in the discharge from the eyes. Dr. Pfingst said that infection of the new-born child has usually taken place in transit. The child may, however, escape infection, and have the poison transmitted to it after birth by uncleanliness of the attendant. Usually within twenty-four hours after infection there is abundant discharge of pus, along with chemosis of the conjunctiva, and swelling of the lids. The disease reaches its acme in from four to ten days, and the swelling of the lids, and chemosis of the conjunctiva recede by the twelfth day. One eye is usually first affected, the disease appearing on the second or third day after birth; while in from one to four days later, the second eye is affected. The disease in the second eye is seldom as severe as in the first. He believes too much reliance is placed on the nitrate of silver, and regards swelling as an indication for cold applications; in this stage of the disease the silver is apt to do harm. Attempts at making applications of silver lead to the aversion of the lids, a manipulation in the performance of which causes abrasions of the cornea, thus providing for the ready entrance of the infection into the deeper structures. His method of applying cold is to have small pieces of linen, or small bits of cotton on a cake of ice, near the patient, and transfer these from the ice to the eye, and change every minute for an hour at a time. After two hours the cold applications are to be renewed as before. Every fifteen to thirty minutes the eye should be opened and flooded with some solution, as boric acid, or sterilized water. He believes the dangerous character of the disease should be thoroughly impressed upon the parents and attendants. After all swelling has subsided, he then begins with a 1 per cent. solution of nitrate of silver, increasing gradually to 3 per cent., making the application once every day, and following each application by irrigation with sterilized water. He has used argonin, experimentally, in a child five days old, and found it less irritating than silver, the disease yielding promptly to the treatment. His experience in two other cases has been equally encouraging.

Dr. DUDLEY S. REYNOLDS, being called on to open the discussion, expressed his approval of the sentiments of the essayist in regard to the irritating effects of nitrate of silver. He said he had not used the nitrate in any case for any purpose, for more than fifteen years. He cited the case of a man 27 years of age, in the second week of gonorrhea, who came to him on Friday evening with the right eye red and watery; the patient complained of a burning sensation in it. He prescribed borate of sodium solution to be instilled into the eye every hour until the irritation subsided, and directed the patient to report the next morning at 9 o'clock. On the second visit the eye was swollen, and there was a discharge of bloody serum mixed with the tears. He at once sealed the left eye with Buller's shield, and sent the patient to the hospital, with the following prescriptions:

℞.	Sodii boratis	℥ iij	96 00
	Sodii chloridi	℥ j	32 00
	Acidi carbolici (C. P.)	ʒ ss	2 00
	Aqua destillatæ	cong. j	4000 00

Misc. Ft. solutio. Sig.—Use as an irrigation for the eye every twenty minutes.

℞.	Balsam copaibæ	ʒ j	4 00

Misc. Ft. capsulæ No. 12. Sig.—Take one every three hours, with a cup of malted milk or beef tea (made of Armour's extract) alternately during the day.

The patient was allowed to drink water *ad lib.* The eyes were directed to be irrigated every hour through the night. This treatment was persistently carried out. The superior periphery of the cornea became clouded. The chemosis of the conjunctiva on the third day was so great that only a small portion of the vertex of the cornea was visible. The lids were simply pulled apart to allow irrigation to be done, no attempt at eversion being made. After the sixth day, the swelling having subsided, and the chemosis still being extensive inferiorly, it was drained out above by a superficial ulceration of the cornea. The treatment was not changed, however. On the eighth day the following was ordered:

℞.	Hydr. bichloridi.	gr. j	065
	Sodii chloridi.	ʒ j	4 00
	Aquæ destillatæ.	℥ vj	192 00

Misc. Ft. solutio. Sig.—Drop into the eye every evening, once after irrigating.

On the twelfth day there was no discharge from the eye, and the bichlorid solution was discontinued, the irrigation being repeated three times a day. The capsules of copaiba were continued all this time. There was now no urethral discharge. On the fifteenth day fluid nourishment was discontinued, and the patient was allowed to go to the table with convalescents. On the seventeenth day he was allowed to leave the hospital, having entirely recovered. The superficial ulceration of the cornea was limited to the periphery. There is to be expected from this plan of treatment almost uniform results, where it can be carried out rigidly. He does not believe anybody but a trained nurse can successfully conduct this treatment.

In closing the discussion, Dr. Pfingst said, he was pleased to hear Dr. Reynolds proclaim his opposition to nitrate of silver, and especially so, as he had suggested a successful substitute. He had formerly seen no case treated without it. He mentioned that Dr. Knapp of New York, had abandoned the nitrate of silver in such cases, and now relies upon ice and irrigation, in both infants and adults. Whether the ice or the irrigation is most important it would be difficult to say. Indications for the cold applications, however, are swelling of the lids. By request Dr. Reynolds gave his views on Credé's method of protecting the eyes of the new-born. He believes it impossible for the eyes to become infected during the period of birth, as the closed lids, protected as they are, at the line of contact, by the lash, over which the vernix caseosa is spread evenly, the pressure of the maternal parts can only secure more complete closure of the lids. The period of incubation of the gonococcus is not greater than twelve hours from the period of inoculation. It will, therefore, appear at once, that it is impossible for inoculation to take place during birth, and show no sign of its presence for twenty-four or forty-eight hours after the birth of the infant; and, it may be truthfully stated that a majority of the cases do not appear until after the third day. He believes the attempt to instill anything into the eyes of the new born should be regarded as meddlesome interference, fraught with mischief only. This opinion is based upon a large experience at the Louisville City Hospital. He has known periods of time when Credé's method of protection was employed, and every eye so treated became subsequently infected with purulent matter. For months at a time, when no interference was permitted, no case of ophthalmia appeared. I am as certain, said he, than ophthalmia neonatorum is nearly always the result of inoculation by the nurse, or others handling the infant after its birth, as I am that three and two make five. He does not believe it possible for the eyes to become infected during the period of birth, excepting in badly managed cases of instrumental delivery. He feels assured that if neither the accoucheur nor the maternal nurse are allowed to touch the eyes of the child, they will almost certainly escape infection. Those eyes alone are in danger which are handled by the same fingers that handle the mother, or are engaged in handling infected persons.

Dr. **Edmund D. Laughlin** introduced the subject of "Minor Surgical Procedures," which in his judgment include the first handling of emergency cases. Many a case of comparatively insignificant injury assumes a more or less alarming gravity and importance by the careless manner of the first handling of the case before it goes to the hospital. He believes that the same antiseptic precautions should characterize the first touch in every case of mechanical injury that surgeons undertaking capital surgery observe. If persons likely to be called on to take charge of the injured or wounded at the time of accident, are to be selected from the laity, they should be properly trained in aseptic methods, in order that no dangerous infection result from the first handling of the patient. If surgeons allow themselves to manipulate injured parts with unclean hands, it can scarcely be expected that persons unfamiliar with the principles of aseptic and antiseptic methods may be safely entrusted to touch the wounded, even in conveying them to the hospital.

Dr. **J. Garland Sherrill** of Louisville read a paper on

PERITONITIS.

He devoted the principal part of his paper to the discussion of the proper management of infected cases. He believes the amount and character of the infecting dose will determine both the degree of severity of the attack and the rapidity of its development. Tuberculous peritonitis is now regarded as clearly a surgical affection. The tuberculous peritonitis characterized by miliary nodules in the walls of the peritoneum, not complicated by tuberculous processes elsewhere, almost uniformly yields to the devices of surgery and no sort of medication will serve even to mitigate or delay the progress of such

In plastic peritonitis, saline purgatives are restorative sometimes curative; in septic cases operation may save medicinal treatment never does. The indications for operation in peritonitis may be stated briefly as follows: When the focus of inflammation can not be reached through the natural outlets, when the patient exhibits anxiety and mental depression. If the pulse is above 140, of diminishing quality, although operative interference may be clearly indicated; the prognosis is grave and no delay should be permitted. He admonishes the profession against the use of opium in all cases, as it diminishes vital energy, obscures the intellect, arrests excretion and masks all the important symptoms by which the surgeon might otherwise be guided in his choice of methods.

Dr. **Ulrich H. Hon** of Bloomington related a case in which he used opium, saline aperients, fomentations, stupes, etc., with a promptly fatal result, the patient and friends declining operative interference. He believed, however, it would be impossible to altogether dispense with opium.

Dr. **Philip C. Holland** related a fatal case in which hepatic abscess ruptured in the inguinal region, discharging one gallon or more of fetid pus. In another case where the inciting cause was appendicitis, operation was followed by returning abscesses and the patient finally succumbed.

Dr. **Thomas A. Hays** thought the general practitioner must have some ready and promptly efficient agent for the relief of pain. He reported an interesting case of appendicitis in which he had consultation, and operative interference was decided necessary; later the patient relapsed and presently a conical tumor appeared in the iliac region. The tumor ruptured spontaneously and the patient discharged large quantities of pus through the bowels. The patient finally recovered. Another case of recurrent appendicitis finally recovered without surgery. He asked whether Dr. Sherrill would advise operative interference in recurrent cases. Dr. Sherrill said in reply that the tendency to recur in appendicitis is one of the characteristics of the disease, and the time to operate is not always easy to determine. He knew of no rule that might be laid down for any considerable number of cases. When rupture takes place into the bowel no operation should be attempted, as recovery will almost necessarily follow. As a general rule, however, he would consider that the danger is far less than the danger of septic peritonitis from rupture. Although opium might be necessary in cases of hepatic calculus, because we have no better means of combating pain, he simply abhorred its use in all forms of peritonitis, and would include in this list all cases of appendicitis.

Dr. **E. D. Laughlin**, whose experience has been large and who was one of the earliest operators in the field, adopting the report of Dr. Buck of New York in 1872, which, after full discussion in the journals, turned out to have an apparently scientific foundation, reported his own first experience in 1875. He well remembered the first case in which he used the knife, evacuating nearly a half gallon of pus from the peritoneal cavity. At that period he made no attempt at excising the appendix, but contented himself with evacuation of the abscess, irrigation of the cavity and drainage. He occasionally sees cases in which aconite and opium with hot or cold applications promptly secures relief. His rule in reference to the selection of cases for operation is this. He practices aspiration daily and as soon as pus appears in the aspirated fluid he operates; otherwise he relies upon medicinal treatment. His patients rarely die. His success is such that he feels entirely satisfied with his method. He regards irrigation and drainage as all sufficient. He asked Dr. Sherrill what he considers the best method of drainage, what kind of tube he prefers, and how he manages to keep it clean.

Dr. **Sherrill** said, in reply, that the best drainage is by means of a glass tube, frequently sucking up the accumulation with a sterilized syringe, thus keeping the tube clear. In cases where there is much oozing of blood, he prefers to secure drainage by packing the wound with gauze, using only the pure sterilized material. In appendicitic cases, where the inflamed area is not in contact with the anterior abdominal wall, he always packs the wound with gauze before operating. He believes that whenever the disease produces a feeble and frequent pulse, with an anxious and careworn expression of countenance, the conditions demanding surgical interference are present. In all such cases he considers it little less than trifling with human life to delay.

Dr. **Ulrich H. Hon** offerred his protest against the sweeping denunciations of opium which had been made in this and other societies. He considers that an agent so long relied upon by the profession and people to relieve pain should not be lightly spoken of. While he uses it sparingly he considers it an absolute necessity, and the chief if not the sole reliance in neuralgia, and the pain of peritonitis, appendicitis and a large class of other afflictions.

Dr. **Sherrill** thought that Dr. Price was rather too radically dogmatic in his denunciations of opiates, and while he himself will not consent to entirely give up its use, he is convinced that the indications for its use are very narrow and diminishing annually. He could scarcely think of any condition, excepting the pain of bilious colic, in which its use could not be dispensed with.

Dr. **Dudley S. Reynolds** said: The hour of necessity for revising and recasting the long established theories of pathology is now upon us. We can have no excuse for prescribing remedial agencies that overwhelm the sensorium, destroying the patient's consciousness of his suffering, when a reasonable familiarity with the principles of pathology might disclose the cause of the pain. If pain is due to local inflammation or simply to blood pressure, opium is positively contraindicated. The salicylates, pilocarpin, saline aperients and electricity may be relied upon in many of these cases; opium never. The so-called neuralgia of anemic persons may be relieved by systematic feeding. The pain of gastro-intestinal irritation, whether due to pressure of distending gases or the local irritation of abnormal ferments, will not only fail to yield to opium, but the patient's life may be endangered by its use, in obtunding the sensibilities of the patient; while dangerous inflammatory processes may be kindled in the intestinal tract. In rheumatic or gouty pains the salicylates act promptly and efficiently; opiates add nervous prostration and still further obstruct all the emunctories, thus aggravating all the conditions of the disease and limiting the chances of reëstablishing active elimination; upon which alone recovery depends. The pain of iritis is nearly always severe, frequently agonizing at night, but it yields promptly to the salicylates and is always aggravated by opiates. The same may be said of the early stages of inflammatory glaucoma. It is better to do nothing where no probable cause of pain can be discovered than to poison the vital centers with opium. Recent pathologic research, with a due consideration of our methods of diagnosis, will nearly always unfold rational principles of therapeutics. Ignorance overwhelms the patient's sensorium and flatters itself that the relief of pain at any cost is a consummation devoutly to be wished. That opium in some form will, for a long time, continue to hold an empiric place in the materia medica I do not doubt. That it has now or ever has had any scientific place I most emphatically deny. It is not a good substitute for atropin in bilious colic; it can not take the place of chloroform as a general anesthetic; its use in diarrhea is not only empiric, but positively pernicious, as it suspends peristalsis, which is nature's mode of expelling dangerous ferments.

On motion of Dr. Burton, a paper entitled "Empyema in Children," by Prof. Philip F. Barbour of Louisville was read by title and referred for publication.

On motion of Dr. Burton, the following Committee on Necrology was appointed: C. F. Askren, U. H. Hon, G. W. Burton and E. D. Laughlin.

On motion the Society adjourned to 8 P.M.

Evening Session.

Promptly at 8 o'clock the Society was called to order by Vice President Sherrill.

Dr. Wm. D. Pennington of West Baden delivered an exceedingly well-written and appropriate Address of Welcome, in which he set forth why a medical society should meet at a health resort, and expressed officially a cordial welcome in behalf of the proprietors of the Springs and the profession of that locality.

At the conclusion of Dr. Pennington's address Dr. Dudley S. Reynolds of Louisville was called on to respond in behalf of the Society.

On motion of Dr. Wm. V. Morgan of Indianapolis, the President appointed the following Committee on Nominations: Prof. P. Richard Taylor, Louisville, chairman; Dr. G. W. Burton, Mitchell; Dr. Edmund D. Laughlin, Orleans.

On motion, the Society adjourned.

Second Day—Morning Session.

The Society met prompty at 9 o'clock, Vice-President J. Garland Sherrill in the chair.

Dr. Elihu P. Easley of New Albany read a paper on

ALBUMINURIA, ITS CAUSES AND SIGNIFICANCE.

He pointed out those delicate changes in the blood supply of the renal organs, varying from slight congestion to inflammation, in which the albumin is eliminated in varying quantities, with or without tube casts; maintaining that elimination of albumin is simply one of the phenomena of blood pressure in the kidneys. Besides a wide variety of local irritants, this condition is often due to derangement of the heart's action. It attends certain organic diseases of the heart, and is a well-known condition in cases of prolonged pyrexia. A variety of toxic conditions of the blood which alter or disturb the blood supply to the kidneys, as well as those which affect their nutrition, are recognized as causes of albuminuria. Finally, it may result from any cause of faulty elimination of the debris resulting from physiologic changes.

Dr. B. Merrill Ricketts of Cincinnati, opened the discussion. He had no doubt that various forms of toxemia caused albuminuria. He recited a case of auto-infection in an aged man with prostatic enlargement, in which albuminuria was a symptom. In acute congestion of the kidneys lumbar nephrotomy has been found an efficient remedy for the constitutional symptoms. At the same time it has been known to promptly correct the albuminuria. It has been employed in both acute and chronic nephritis. In cases attended with general dropsy, drainage relieves the overtaxed renal organs. In a desperate case, Dr. Ricketts opened the abdomen, evacuating an enormous quantity of fluid and irrigating the peritoneal cavity with a normal solution of chlorid of sodium. He kept up the drainage by means of a tube, which he retained in the abdominal wall. The patient lived in comparative comfort for ten weeks. Muscular debility was greatly relieved by massage, while the symptoms of impending suffocation were completely controlled by peritoneal drainage. The amount of albumin in the urine was not altered in this case, but it is certain that the patient's life was greatly prolonged, and the state of his existence rendered vastly more tolerable.

Dr. John L. Masters of Indianapolis, has observed in cases of albuminuria, attended with retinitis, that in proportion as changes in the retina would diminish by dietic and constitutional treatment, the albumin diminished *pari passu;* and he has no doubt of the fact that blood pressure, if not the cause, is a constant companion of that form of retinitis so often found in persons with albuminuria.

Dr. Sherrill recited the case of a woman with pelvic disease, suffering with albuminuria, and a grave form of heart lesion. The necessity for surgical interference was so great that chloroform was administered, and an operation done, relieving the patient of a painful, and almost intolerable state, without influencing either the condition of the heart, or materially altering the amount of albumin in the urine. As a rule he fears to operate in such cases. In emergencies, however, he considers the use of chloroform comparatively safe.

Dr. Ricketts, in answer to a question, said there was no contra-indications to necessary surgery in the mere presence of albumin, even with tube casts.

Dr. E. D. Laughlin reported the case of a man 27 years of age with albuminuria, hyaline tube casts, and occasional attacks of hematuria. In this case the salicylate of sodium and bicarbonate of potassium in an infusion of gentian, regularly administered, gave prompt relief to the distressing headache, and finally brought about complete recovery. This was a desperate case, and extremely unpromising, but two years have now elapsed since the treatment was discontinued, and the man remains robust, strong and hearty, thus verifying Dr. Reynolds' views concerning the value of the salicylates in nephritis, as well as other local inflammations.

Dr. Easley, in closing the discussion, related a case of a pregnant woman who was promptly relieved of albuminuria by an infusion of stigmata maydis. As pregnancy advances, the disease may return, and it may be that other measures will have to be resorted to.

Dr. B. Merrill Ricketts of Cincinnati, read a paper entitled

PROLAPSE OF THE RECTUM, AND HEMORRHOIDS.

He denounces Whitehead's operation, and likewise what is known as the American operation. He considers postural treatment an important adjunct. He also believes that postural habits may greatly obviate the liability to prolapse of the rectum. In chronic cases of prolapse, of the third and fourth degree, he believes that section, and anastomosis offers the best means of relief. This, however, is by no means the only method to be employed. In extreme cases of the fourth degree he has for a long time practiced the process of reefing the intestine by a submucous ligature introduced by passing a small semi circular needle into the mucosa, keeping the point as nearly within the muscular wall of the tube as possible; the needle being armed with kangaroo tendon is brought out at the point of entrance, having described a complete circle. This tendon is then tied up tightly, and in the same horizontal plane a second, and then a third suture completes the necessary folding up or reefing of the tube. This folding together of the intestine is preferable to any attempt at invagination, as the subsequent inflammatory adhesions incorporate the confined tissues of the mucosa into a conglomerate mass with the surface of the muscularis. A second operation in the same case may be necessary to complete the reduction of the prolapse. This is rarely necessary, however, even in cases of the fourth degree. After a series of elaborate experiments in the preparation of suitable material for a suture, he has been led to prefer the kangaroo tendon because it may be relied upon to remain *in situ,* without softening, for at least thirty days, giving ample time to secure a fixed position of the parts in their new relation. In preparing this tendon for use he warns the profession against formalin, because it is not only highly irritating to the tissues, but makes the tendon friable, and insecure from its liability to break. Dr. Ricketts exhibited his needle, and presented each member of the society with one. It is curved about 195 degrees, and represents a section of a circle about two and one half inches in diameter. It is simply a strong steel needle.

Dr. Wm. V. Morgan of Indianapolis, has occasionally been rewarded with satisfactory results after linear cauterization. He has been occasionally successful, in cases of the first and second degree, by the introduction of kangaroo tendon just within the mucous line of the anal orifice, completely encircling the rectum at the inferior border of the sphincter. Placing one finger in the anus the kangaroo tendon is tied tightly and the knot pushed in so as to bury it from sight. This amount of contraction by a sort of puckering string, sets up irritation, restores activity to the contiguous muscular fibers, and secures the patient from a tendency to prolapse. He thinks that Dr. Rickett's operation is perhaps better in cases of the third and fourth degree. He has occasionally practiced the method of dilating the sphincter by passing one finger at a time until the whole five were introduced, pushing the hand up in the rectum as far as the sigmoid. Where dilatation has been practiced in this manner, good results have frequently followed.

Dr. RICKETTS, in conclusion, spoke of excision of the rectum as high as the sigmoid, in severe cases. He expressed his unalterable opposition to clamp and cautery, which he has reason to believe is too often followed by secondary hemorrhage. He thinks there are some operators who advocate this plan, who could throw a good deal of light on the subject if they felt so inclined.

The next paper was

LACERATED WOUNDS OF THE EYE

By Dr. DUDLEY S. REYNOLDS of Louisville. He recited a number of cases of severe injuries to the eye in which ultimate recovery followed. One was an extensive laceration of the cornea, iris and crystalline lens, with a foreign body which had been in the eye for five days. The foreign body being removed, iridectomy was done and the lens underwent slow absorption, resulting in complete recovery, with good vision. Another case of a stone cutter, who had extensive laceration of the cornea, the iris and lens being involved, iridectomy was done and the lens extracted at once. In this case recovery followed. This patient returned to his business for several years and finally took charge of a small store, kept a set of books, and enjoyed good vision until the time of his death, which occurred recently. Another was a case of extensive laceration of the sclera, evacuating a large amount of vitreous humor and rupturing the capsular ligament of the lens, allowing the iris to protrude through the scleral wound. Iridectomy, with suturing of the scleral wound, was followed by recovery. The eye becoming cataractous, the lens was extracted eleven years subsequent to the original injury; and on April 13, 1897, the opaque capsule in this eye was divided with needles and the patient with +16.00 D. was able to read No. 1 Snellen. Although the field of vision is greatly contracted, acuity of perception is perfect. He recited another case of interest in which a guncap had produced an extensive laceration of the sclera, exposing the ciliary muscle. The wound united promptly, leaving the eye apparently free from any irritation. Remaining so for a few months only, it became irritable, and subsequently developed a typical form of inflammatory glaucoma, with ultimate loss of sight, and sympathetic irritation in the fellow eye, necessitating enucleation of the injured eye, and iridectomy in the fellow eye. Sight is so impaired that the man can not see to read, although he is able to pursue the business of a farmer.

Dr. JOHN L. MASTERS of Indianapolis, opened the discussion by calling attention to the great gravity of slight injuries where infection of the wound takes place. He pointed out the almost inevitable certainty of loss of sight in those eyes which are pierced by foreign bodies which can not be located and removed. He recited thé case of a penetrating wound followed by absorption of the lens, in which good vision was ultimately obtained. Another case was cited, of a man shot in the face, destoying one eye, the other one being slightly injured. The destroyed eye was enucleated; there were no evidences of a [illegible] body in the other eye. In time it became irritable and [illegible]dy; general treatment afforded temporary relief. Ophthal[illegible]opic examination showed a gray mass in the anterior por[illegible] of the choroid. Recurring attacks of dimness of sight, [illegible]panied by irritation in the eye has been finally followed [illegible] cataract, and now there is bare perception of light. He thinks the cases recited by Dr. Reynolds are of great interest to every member of the profession, but they should be looked upon as extraordinary cases. They illustrate what may be accomplished when the foreign body can be removed from the eye.

Prof. P. RICHARD TAYLOR of Louisville, wished to emphasize the importance of the case recited by Dr. Reynolds, of the man whose eye was injured by the guncap as affording additional evidence of the unfavorable character of injuries of the ciliary muscle or ciliary body. Cicatricial formations in the ciliary muscle or body imprison the nerves and keep up a perpetual state of irritation and finally provoke the so called sympathetic inflammation, followed by blindness.

Dr. Masters might have added to his list of dangerous wounds from penetrating bodies, a large class where the infecting material enters with the foreign body; the infection being thus carried directly into the eye, inflammation is excited at once. It is therefore not sufficient that the foreign body be located and removed, but we should be well assured that no infection has accompanied the injury, otherwise we should at once enucleate the eye, and save the patient a prolonged period of suffering and the dangers of constitional infection, which have occasionally been overlooked with fatal result to the patient.

Dr. ULRICH H. HON of Bloomington presented a specimen of uterine mole, or hydatiform degeneration in the chorion. The patient was suffering with hemorrhage, and had voided a large mass of this material. On examination a considerable amount of retained cystic matter was removed, and the hemorrhage ceased. There was more than enough to have filled a quart vessel. The condition, though rare, is sufficiently well known. The mass resembles a collection of hydatids, being made up of a minute series of spheroidal cysts, which are the degenerate remains of the villi of the chorion.

Dr. WM. V. MORGAN pointed out the fact that these remains are, in medico-legal cases, always accepted as the products of pregnancy.

Dr. WM. J. PURKHISER of Salem read a paper on

MEDICAL EXPERT WITNESSES AND EXPERT TESTIMONY.

He pointed out the lamentable fact that courts of justice sometimes accord the distinction of expert to a thoroughly incompetent medical witness, thus continuing to bring the profession into ridicule. He thinks a better knowledge of medical jurisprudence is necessary to the maintenance of the dignity of the profession in medico-legal inquiries.

Dr. DUDLEY S. REYNOLDS opened the discussion by pointing out the character of the preparation which the law requires of a medical expert witness. He maintains that medical jurisprudence is one of the most important subjects taught in the medical colleges, and that it is not sufficiently appreciated by many institutions. If the medical expert witness duly informs himself in relation to the subject about which he is going to testify, carefully avoiding any manifestation of bias in opinion, he may escape the suspicion of having a personal interest in the success of the party-litigant in whose interest he was summoned. It is not expected that every man knows everything, and the medical expert witness should not hesitate to express his ignorance about matters concerning which he is uninformed; but the court will not hold him guiltless if that ignorance includes any matter of general information in the profession.

Dr. B. MERRILL RICKETTS spoke of the treatment of the medical expert witness by expert lawyers, who never lose an opportunity to bring the medical profession into ridicule when this testimony is damaging to one side or the other. He has a habit of defending himself on the witness stand, and recently had occasion to say to the judge and counsel that they knew nothing of such matters as the shortening of a leg after fracture. He defended himself by showing the ridiculous character of the questions of the counsel, and demanded the right to make himself understood to the jury and court, in the definition of a difference in the results of injuries in the thigh bone of children and adults.

Prof. P. RICHARD TAYLOR, chairman of the nominating committee, reported as follows: For president, J. Garland Sherrill of Louisville; vice-president, Wm. D. Pennington of West Baden; secretary and treasurer, George W. Burton of Mitchell; corresponding secretary, Ulrich H. Hon of Bloomington.

Executive Committee: Dudley S. Reynolds, Louisville; B. Merrill Ricketts, Cincinnati; Elihu P. Easley, New Albany; Edmund D. Laughlin, Orleans; William V. Morgan, Indianapolis.

The special committee on necrology reported through its chairman, Dr. Askren, a series of resolutions on the deaths of ex-presidents Riorden of Bedford and Charlton of Seymour.

The committee on sanitation and State medicine, of which Dr. U. H. Hon was chairman, reported a series of resolutions which were adopted. The committee was continued, with instructions to secure suitable papers, from the best informed persons, for the purpose of elucidating the recent sanitary laws of Indiana, to be made the subject of special consideration at the next meeting.

The chairman of the executive committee was instructed to arrange suitable railway concessions for the next meeting of the Society.

On motion, the Society adjourned to meet at West Baden Springs, Dec. 28 and 29, 1897.

PRACTICAL NOTES.

A Remedy for a Form of Tinnitus Aurium.—Dr. F. Steiner (*Arch. f. klin. Med.*, lviii, 2, 3) in discoursing upon his conclusion that polyneuritis is a frequent complication of acute rheumatism, the basis being probably an epineuritis, recommends the fluid extract of ergot as a remedy for the tinnitus aurium caused by the long continued use of sodii salicylate and potassii iodid.

The Treatment of Exophthalmic Goiter by Section of the Cervical Sympathetic.—Reclus and Faure (*Gaz. Hebd. de Méd. et de Chir.*, June 24, 1897, p. 592) have reported a case of exophthalmic goiter occurring in a woman in her third pregnancy and following emotional disturbance. Medical treatment had been without benefit and electricity brought only passing amelioration. The exophthalmos was so pronounced that the eyelids could not be closed and the corneæ had suffered from the want of protection. The thyroid gland was greatly enlarged; the pulse ranged between 120 and 130; and the constitutional disturbance was profound. The cervical sympathetic was readily resected on either side through an incision along the posterior border of the sterno-mastoid muscle and improvement speedily ensued. By the seventh day the exophthalmos had almost entirely disappeared and the ulceration of the cornea had cicatrized. The swelling of the neck had diminished; the pulse was reduced to 90; the trembling was less marked; and the general condition was greatly improved.

Surgical Treatment of Tumors and Enlargements of the Thyroid Gland.—Paul (*British Medical Journal*, July 3, 1897, p. 1) reports twelve cases of adenoma of the thyroid gland, five of parenchymatous goiter and six of exophthalmic goiter treated surgically, and details the histologic appearances found in the structures removed. In the first twelve cases tumors weighing up to three-quarters of a pound, and in the remainder portions of the gland, some of a very considerable size, were removed, without a fatality. Healing was rapid in all, only a few patients being under surgical treatment more than a fortnight. In six of the cases of adenoma there was complaint of constitutional symptoms, and in all of these young active gland-tissue was present; in the remaining six, symptoms of mechanical obstruction only were present. In the latter the tumor was very small, colloid, fibrous or almost entirely cystic, with little or no active secreting epithelium. The patients suffering from mechanical obstruction alone were entirely relieved by the operation, while those in which constitutional manifestations also were present were additionally relieved or very much improved in regard to these. Of the five cases of parenchymatous goiter sufficient time had elapsed after the operation in only two to permit of the expression of an opinion. The removal of one lobe was followed by atrophy of the other lobe, with the establishment of perfect health and freedom from symptoms of myxedema. The immediate effect of the operation in the cases of exophthalmic goiter consisted in a marked amelioration of all the symptoms. In some cases the first improvement was so decided as to appear remarkable and to leave no doubt as to its relation to removal of thyroid tissue. This early improvement may be followed by slow progress, so that several years must elapse before a final judgment could be given.

Successful Treatment of Internal Aneurysms with Injections of Solution of Gelatin.—Lancereaux has tried injecting 50 c.c. of a sterilized 1 per cent. solution of gelatin in a 1 per cent. salt solution at 37 degrees C., as Dastre announced in 1895 that a solution of gelatin injected into the veins of a dog renders the blood much more coagulable. Lancereaux reported at the Académie de Médecine (*Bulletin*, June 22), the one case in which he has tried this treatment. The patient was a man of 46 who had been affected with an aneurysm of the first part of the arch of the aorta for two years. It had become as large as the head of a child, 14 x 15 centimeters, and was rapidly increasing with distinct expansive pulsation; the accompanying oppression and pain, dyspnea, etc., were most distressing and the thinness of the wall showed that the aneurysm was on the point of bursting, when the injections of gelatin were made as a last resort. Twelve injections as above (January to May) relieved the patient of all his pain and reduced the size of the tumor 2 centimeters. It has grown firmer and the pulsation is no longer radiating but with the aortic current. He left the hospital to attend to his usual occupations, saved from certain death by this harmless and evidently efficient treatment, the only one known for internal deep aneurysms beyond the reach of surgical intervention. A slight redness at the spot of the injections in the gluteal region and a slight transient increase of temperature after the first injection were the only inconveniences.

Instrumental Evacuation of the Uterus.—Doléris has a comprehensive article in the *Journal de Méd. de Paris* of June 20, on the treatment of incomplete abortion. He states that instrumental evacuation of the uterus is neither a difficult nor dangerous operation, if it is performed with extreme gentleness and care, *without chloroform*, the bladder emptied first, using the fenestrated forceps, the swab and the curette as indicated, an attentive assistant pressing down the fundus, with repetition of the dilatation in the course of the operation and frequent intra-uterine and abdominal palpation, and the traction of the cervix with *three*-pronged forceps. He concludes by swabbing out the uterus with creosoted glycerin and a copious irrigation at 40 degrees with a dilating sound, finally packing it with iodoform gauze very slightly impregnated with creosoted glycerin at 5 per cent. (The gauze loses its absorbent powers if much impregnated, besides irritating the vaginal mucosa.) He renews the dressing every two or three days, with an intra-uterine irrigation each time. In 44 hospital cases of curetting the gravid uterus (33 post-abortum and 21 post-partum), he has had neither accidents nor death.

Cholecystitis Complicating Typhoid Fever.—Mason (*Boston Medical and Surgical Journal*, May 13, 1897, p. 449) has reported the case of a woman, 30 years old, who came under observation in the third week of an attack of typhoid fever, with dry brown tongue, palpable spleen, rose spots and distended abdomen. Anorexia, vomiting and constipation had been prominent symptoms. Widal's serum test yielded positive results. There was no leukocytosis. Toward the end of the third week the patient complained of increasing abdominal pain that became localized in the right hypochondrium, where a tumor four inches in diameter developed, extending from the costal border toward the umbilicus. The swelling was very tender, absolutely dull on percussion and descended on full inspiration. The patient presented appearances of collapse and it was feared that rupture of the gall bladder distended with pus would take place. Celiotomy being concluded to be too grave an operation to undertake under the circumstances, the gall bladder was tapped at a point an inch below the costal margin and four and a half inches from the umbilicus. Three and a half ounces of sero-purulent fluid were withdrawn, pale in color, looking more like urine than bile. The aspirating needle moved up and down with the action of the diaphragm. No gallstones could be felt with the point of the needle. After its withdrawal a pad and a swathe were applied to prevent the escape of septic fluid into the peritoneal cavity. The relief to pain was immediate. On the next day all of the urgent symptoms had disappeared and they did not return. The pulse fell from 140 to 120 and defervescence followed in five days. The gall bladder gradually retracted; convalescence ensued, and when the patient returned for observation after a month nothing abnormal was found in this region. Examination of the fluid removed disclosed the presence of microörganisms that yielded the various reactions of typhoid bacilli.

The Radical Cure of Hernia by Implantation of Sterilized Sponge. As the result of experimental observations upon rabbits in the Physiological Laboratory of the Johns Hopkins University, Platt (Johns Hopkins *Bulletin*, March, 1897, p. 41) was led to attempt implantation of sections of sponge in the inguinal canal for the purpose of forming a firm connective tissue barrier to the descent of the bowel and adnexa in the radical-cure of hernia. In the actual application of the method an incision about two and a half inches long is made directly over the inguinal canal, following its course, the lower end extending about half an inch upon the scrotum. If the hernia is down the operation is so much the easier. The canal if laid freely open. The sac, whether congenital or acquired, is opened in its entire length, the hernial contents reduced and the sac cut away close to the ring if congenital, while if acquired it is cut square off after being ligated as high up as possible and dropped beneath the ring. In the case of the congenital sac it is often necessary to leave the thin inferior layer *in situ* and adherent to the cord. Next a section of fine firm surgical sponge is cut about an inch and a half in diameter and an eighth of an inch in thickness. This is sterilized without boiling by immersing in a solution of soda, washed in sterilized water, treated with potassium permanganate and oxalic acid and then thoroughly washed in sterile normal saline solution. A radical cut is made in the section. The constituents of the cord are gathered together as high up as possible and placed in the center of the section and at a right angle to it. The edges of the cut in the sponge are now overlapped slightly and two sutures are inserted into the sponge to keep it in place on the cord, which now pierces its center. The section of sponge is spread out beneath the internal ring and the conjoined tendon is sewed firmly by two or more quilted sutures to Poupart's ligament, using a needle in a handle. The inguinal canal is now snugly sewed up with silk sutures and over all the skin is sewed with silkworm gut. It is absolutely necessary to use some kind of drainage at the upper angle of the wound, as there is invariably some serous oozing and swelling. This may be removed in twenty-four hours. The patient is confined to bed upon his back for three weeks. If a boy, it is well to use the Bradford frame, to keep him from sitting up and twisting about in bed. The skin sutures are removed on the ninth or tenth day, the wound being treated on ordinary antiseptic principles. After three weeks the patient is permitted to sit up in bed for a day or two; then he sits up for two or three days in a chair, and afterward he goes about as usual. It is unnecessary to use any support over the site of operation beyond a light strip of gauze to protect the fresh cicatrix from friction.

The Bacteriology of the Follicular Enteritis of Children.—The *British Medical Journal* quotes an article by Dr. Finkelstein of Heubner's clinic, from the *Deutsche medicinische Wochenschrift*, regarding two forms of the gastro-intestinal enteritis of infants that appear to be due to an infection. The source of the contagion lies in the stools. Two groups of the disease are to be distinguished, the dysenteric and the toxic. The actual cause of the disease must therefore be able to give rise to irritation of the mucous membrane, and to produce toxic products. The bacteriologic examination of the purulent masses in the author's case showed the presence of abundant rod-like microörganisms contained in the pus cells, and varying much in appearance. Often they were arranged in twos. All the different forms were shown to belong to a single microorganism. By cultivation a microbe possessing extraordinary resemblance to the bacillus coli communis in almost pure culture was obtained. The author then details his inoculation experiments. In mice it produced, when introduced with the food, a disease very like Löffler's mouse typhoid. The morbid appearances corresponded exactly to those described by Heubner as taking place in the epithelium in cholera infantum, but ulcerative processes were absent. The microörganism is only present in the glands, and hence the death of the epithelium must be due to a toxic action. The bacillus is also able to produce remote toxic effects. Growth on potatoes showed differences from that of the bacillus coli, otherwise the differences were rather those of degree than kind. Experiments on animals yielded more important results. Virulent cultures of the bacillus coli were shown not to be able to act pathologically on healthy mucous membrane. A close relationship existed between the bacillus in question with the bacteria known to produce the manifestations in meat poisoning. Thus it does not appear correct to class this microörganism as the bacillus coli. The virulence of the microörganism varies greatly, and can be diminished by culture. As regards its pathogenic properties, it was found constantly present in over fifty cases of typical enteritis and colitis dysenterica. All cholera-like forms must not be grouped as follicular enteritis. If the microbe has lived and flourished in the milk consumed, the symptoms of intoxication may begin forthwith. It may be said that follicular enteritis passes through the stages of dyspepsia, intestinal catarrh, up to a cholera-like disease. When the intestinal epithelium is destroyed, the bacillus may get into the blood stream and produce a septicemia as well as hemorrhagic purulent metastases. Mixed infections are common. There are two forms of the general infection: one resembling typhoid, and the other giving rise to high fever, collapse and rapid death.

Partial Rupture of the Spinal Cord Without Fracture of the Spine.—Watts (*British Medical Journal*, March 13, 1897, p. 654) has reported the case of a man 65 years old, who while partly under the influence of alcohol fell from a cart that he was driving. He was able to arise and walk to his home, a distance of a mile, where he put his horse away and sat down in a chair by the fire. His neck felt a little stiff, but it was free from pain. Three hours from the time of the accident the man noticed that he had no power in his right hand, then that his left hand was paralyzed and then that he could not move his legs. The paralysis came on so rapidly that it seemed to affect all of the limbs almost simultaneously. When the patient came under observation, two days after the accident, the respiration was entirely diaphragmatic. He answered questions rationally and presented no cerebral symptoms. Movement of the neck caused pain, but there was none when the head was held still and none in the course of the nerves. There was no bruising of the skin and no irregularity of the spinous processes. The patient was able to raise his arms from his sides to a horizontal position and he could also move them across his chest. He could flex but not extend his forearms. He could make no movement of hands or fingers. The knee jerks and the plantar jerks were wanting. Sensation was lost upon the trunk and lower extremities below the level of the third costal cartilage; there was no hyperesthesia above this level. There was loss of sensation also on the anterior and posterior surfaces of the forearms, on their inner halves, on the whole dorsum of the hands, on the inner part of the palms and on the palmar aspects of the little fingers. There was retention of urine and the bowels were constipated. The pulse was 56, full and regular. The temperature was subnormal. The urine contained a trace of albumin. No alteration in the extent of the paralysis or of the aresthesia was noticed and the patient's mind remained clear until his death, which took place twelve days after the accident from edema of the lungs. Upon postmortem examination the spinal dura mater was found to be torn transversely across in its left half and the cord beneath was likewise torn across for a corresponding extent. On antero-posterior section the cord was seen to be soft in consistence and grayish in color at the seat of rupture and for a half inch above the superior limits of the gray area being indistinctly defined by a somewhat irregular transverse line. This condition appeared to exist throughout the entire transverse extent of the cord. The rupture was seated exactly opposite the articulation between the sixth and seventh cervical vertebræ; a little movement was possible at this joint, but the posterior common ligament was intact and there was no evidence of fracture.

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:
Per Annum, in Advance $5.00
Single Copies . . . . 10 Cents.

Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 61 Market Street (Occidental Buildings), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, Venetian Building, Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the *Editor*, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

INFORMATION WANTED.

It would greatly facilitate the prompt delivery of the JOURNAL to those members of the ASSOCIATION living in large cities, if they would kindly furnish this office with their street address in those cases where it is omitted from the wrapper of their JOURNAL, as we have been notified by the postmasters of the larger cities that second-class mail matter not having street address, would be placed in the general delivery to await call.

SATURDAY, JULY 31, 1897.

THE ANTIVIVISECTION BILL.

We notice that the esteemed Senator GALLINGER of New Hampshire is extremely anxious about his antivivisection bill. The following occurred on the presentation of the Memorial of the AMERICAN MEDICAL ASSOCIATION on the subject—*Congressional Record*, July 2, 1897:

MR. COCKRELL. "I present resolutions unanimously adopted at the annual meeting of the AMERICAN MEDICAL ASSOCIATION in Philadelphia June 2, 1897, remonstrating against the passage of Senate bill No. 1063, for the further prevention of cruelty to animals in the District of Columbia. I ask that the Memorial lie on the table and that it be printed as a document."

The VICE-PRESIDENT. "Without objection, that will be the order."

MR. GALLINGER. "I will inquire as to what is the Memorial particularly?"

MR. COCKRELL. "They are resolutions opposing the vivisection bill reported by the Senator."

MR. GALLINGER. "Resolutions adopted by a medical association?"

MR. COCKRELL. "Adopted by the AMERICAN MEDICAL ASSOCIATION at Philadelphia."

MR. GALLINGER. "In this connection I desire to state that I entered a mild protest a while ago against the printing of numerous documents relating to this one bill. We have, I think, four or five different documents already printed. Some of them are in severe and unjust criticism of the committee, stating absolute untruths regarding the action of the committee. I do not object to the printing of the Memorial, and yet it does seem to me rather strange that when a committee has considered a matter carefully, giving a long hearing to both sides, permitting the opponents of the bill to print 300 pages in the report of statements in opposition, that they should then flood the Senate with memorials, resolutions and protests, and that we should print them at the expense of the Government."

MR. COCKRELL. "This Memorial consists of only two or three pages, and it is in appropriate form."

The VICE-PRESIDENT. "The Memorial will be printed as a document, in the absence of objection, and referred to the Committee on the District of Columbia."

It does not appear that there is need of any particular comment upon it, except to show the hostile attitude that the Senator has taken.

IDLENESS AND INSANITY IN PRISONS.

The following press dispatch tells a tale that perhaps deserves some editorial comment from a medical point of view:

> New York, July 22.—Since the anticonvict labor law went into operation on January 1 twenty prisoners in the Kings county penitentiary have lost their reason. Madness began to assert itself without anything to attract public attention. It attacked the victims one at a time until last week, when nine convicts, under the dull torture of enforced idleness, went mad. Five of these unfortunate men were removed yesterday from the penitentiary to the State asylum at Matteawan. The remaining four will probably be disposed of today. Three are federal prisoners and their destination is the asylum at Washington. Madness in one case is laid at the door of mental torture, long sustained. In all the other cases enforced idleness—twenty hours of each day passed behind iron bars in trap-like cells—seems to give the explanation. The increase of lunacy as shown by figures among the male convicts is alarming. The records of 1890 show one case of lunacy; in 1891, three; in 1892, one; and for the three following years a total of four. Then prison work fell off and for the first seven months of 1896, a period corresponding to the time during which the anticonvict labor law has been in operation, nineteen prisoners lost their reason.

The prophecy was made when a similar measure was being pressed prohibiting convict labor in another State than New York, by the head of one of the chief penal institutions, that the result would be so large an increase of lunacy amongst the convicts that they might as well turn the prisons at once into asylums, only reserving a space for the necessary and inevitable preliminary lapse from reason to occur in. This was uttered as a rather forcible statement of the probable outcome of such a law as it appeared to him, but it is one that contained a large element of truth and only a moderate amount of exaggeration. Idleness and confinement would tax the resistance of an intellect that has abundant resources, and much more the untrained and more or less degenerate brain of the average prison inmate who has necessarily to be deprived to a large extent of the saving influences of companionship and association with his fellows. From a purely philanthropic point of view it is not a justifiable piece of legislation to enact laws that deprive men of their reason, and it may be a question whether if tested it might not come under the constitutional prohibition of cruel and unusual punishments. In case of prisoners convicted before the passage of such acts, they constitute in spirit and in fact, if not in law, a most cruel and inhuman aggravation of the punishment to which they were sentenced.

There is an economic as well as a humane aspect in which the facts may be considered. Mental breakdowns under such conditions is not the most hopeful type of insanity and it promises to largely increase the burden upon the community. A convict may reform, many of them do to a certain degree, and make harmless if not very valuable members of society. It is the aim of philanthropists to bring this about and to make penitentiaries reformatories rather than places of vindictive punishment. If their function is to become manufactories of chronic dements it will be of very little advantage; the insanity added to the original evil tendencies will hardly make them any safer for the community while it will insure their becoming dependents upon the taxpayers. In no way it can be viewed is the anticonvict labor legislation advantageous or respectable.

It is probable that the labor unions and others who have favored these acts, gave very little attention to any possible consequences except the immediate results they had in view. It would not be creditable to them to suppose they would deliberately wish to condemn all convicts of all grades of guilt to a possible and even probable fate that is commonly described as almost or altogether worse than death, however true this may be, and yet this is just what they have practically done. It is useless to say that they can be employed without competition with outside labor, for if that were possible it would have been resorted to in the New York institution—it must be presumed that it was either impracticable or was made so by the wording of the law; no prison authorities would readily abandon their best resource for government as well as for profit in such institutions.

This is only one of many instances where inconsiderate law-making is done that ought to have been modified or avoided. If enlightened medical counsels could prevail, if medical men could take part in making our laws, or if something besides what is called practical politics could be more considered by our legislators, such a disgrace to the State as this inhuman and backward step in prison administration would have probably not occurred. It is not at all necessary that prison labor should injuriously compete with workers outside, but the outcry at the present time is too indiscriminating, and inconsiderate legislation is too often demanded with such results as are shown in the paragraph quoted.

THE NATURE, DIAGNOSIS AND TREATMENT OF COLLATERAL HEMIPLEGIA.

It is not our purpose here to dwell upon the diagnostic features of the various forms of paralysis of cerebral origin or upon the difficulties that not rarely attend their differentiation. We wish rather to refer to an interesting observation made by Ortner (*Deutsche medicinische Wochenschrift*, June 10, 1897, p. 372), in connection with cases of hemiplegia in which palsy and cerebral lesion are on the same side of the body—collateral hemiplegia—in contradistinction from the cases in which the two are on opposite sides—contralateral hemiplegia—and which if verified will prove an exceedingly valuable aid in diagnosis, as well as an important guide in treatment.

Ledderhose maintains that in cases of hemiplegia dilatation of one pupil, and more especially unilateral papillitis, upon the same side as the paralysis of the extremities is indicative of a lesion upon the same side of the brain. Both of these symptoms are, however, so uncommon under the conditions in hand that they are of little actual diagnostic aid. The peculiarity that Ortner points out as distinctive of collateral hemiplegia consists in the manifestation of greater respiratory activity upon the side of the chest corresponding with that of the flaccid muscles than upon the opposite apparently unparalyzed side. In ordinary cases of contralateral hemiplegia this insufficiency of the respiratory muscles is noted upon the same side as the weakness of the extremities, or of the face and tongue, that is, that opposite to the seat of the lesion.

In explanation of the apparently paradoxic relation between the distribution of the paralysis and the seat of the lesion in the cases of collateral hemiplegia it has been suggested that there may be imperfect, or even total failure of, decussation of the pyramidal fibers in the medulla, but of this proof is yet wanting. It has also been thought that the result might represent the indirect influence of the affected hemisphere upon its uninjured fellow, but such a condition should then be common and attended with paralysis of both sides of the body, more pronounced upon that opposite to the situation of the lesion. A similar objection may be lodged against the view that the disturbance is a more general one, such as may result from diminished consistency or edema of the second half of the brain. That the palsy might be attributable to an undiscovered lesion in the opposite hemisphere seems in the highest degree improbable and it is not more likely that it owes its origin to representation of both sides of the body in the cortex of each hemisphere.

The most probable explanation is that which attributes the condition commonly to an extra-cerebral (meningeal), cortical or subcortical lesion, causing primarily general muscular resolution and secondarily irritation of the muscles upon the opposite side of the body. As a result we have a tonic state of the muscles upon this side and a flaccid state of those upon the other (same side as the lesion), without, however, interfering with the activity of the muscles of respiration upon the latter side. The most common condition that gives rise to this train of phenomena is hematoma of the dura or internal hemorrhagic pachymeningitis, of which the symptom under consideration may be considered in some degree diagnostic.

In a study of thirty-five cases of collateral hemiplegia it was found that the onset was attended with loss of consciousness in twenty-four; and of thirty-eight cases the lesion was situated in or adjacent to the cortex in twenty-six, the internal capsule and the fibers passing through it escaping in all. Of twenty-seven cases of intracranial lesion in or about the cortex, with hemiplegia upon the same side of the body, in not less than seventeen was the lesion extracerebral, and in thirteen of these it consisted of hematoma of the dura or hemorrhagic pachymeningitis. From these facts the conclusion seems justified that so-called collateral hemiplegia is a relatively common manifestation of either hematoma of the meninges or internal hemorrhagic pachymeningitis and the diagnosis of these hitherto obscure and latent conditions is facilitated by the recognition of apparent paralysis of the members of one side of the body with unimpaired respiratory activity upon the same side.

The state of the respiratory activity is also a diagnostic index in cases in which symptoms of bilateral cerebral irritation exists, as failure of this function upon one side under these circumstances is indicative of the existence of an intracranial lesion upon the opposite side, alone or at least in preponderant degree. The establishment of a correct diagnosis in some cases of the kind under consideration will suggest surgical intervention, with a reasonable prospect of finding the lesion, and in many instances also of successful removal of the source of irritation and paralysis, with consequent recovery and saving of life. Ortner is able to report five cases in which a correct diagnosis was reached upon the basis of the phenomenon to which he has called especial attention.

THE EFFECTS OF THROMBOSIS AND EMBOLISM OF THE CORONARY ARTERIES.

Instances of thrombosis and embolism of the coronary arteries of the heart, the resultant functional disturbances of which can be carefully studied, are of great value and interest because of the light thus thrown upon the circulatory conditions in the myocardium of man. Such cases sometimes furnish conditions that may be said to correspond to circumstances produced by well planned physiological experiments.

A recent and instructive case of this kind is one of thrombotic occlusion of the main stem of the right, and embolic occlusion of the left, coronary arteries of the heart in a 32 year old man reported by Chiari[1] of Prague.

The postmortem examination showed, as indicated, that the patient had died from complete occlusion of both the coronary arteries. The very beginning right coronary artery was occluded by a thrombus which had developed some days before death and which had been followed by myomalacic foci surrounded by beginning reactive changes. The left coronary artery was closed by the embolism of a fragment of the thrombus in the right coronary vessel. This embolism was the immediate cause of death. It occurred a few minutes before death and gave rise to a sudden collapse that lasted but a few minutes before the final stopping of the heart's beat. The cause of the thrombosis is referred by Chiari to a, for such a young person, quite marked sclerosis of the beginning of the aorta and to the presence of a chronic nephritis. Of the cases in the literature that are in the main identical with this, Chiari mentions those reported by Hammer,[2] Oestreich[3] and Barth[4]. In Oestreich's case it concerns a 32 year old man that died suddenly. Above the orifice of the right coronary artery was a pedunculated thrombus attached to the wall of the aorta; this thrombus covered exactly the ostium of the artery. In the left coronary artery was a long, yellowish-gray embolus. Barth's case was one of occlusion of the opening of the right coronary artery by a thrombus in the corresponding sinus Valsalvæ due to a beginning sclerosis at this point. A but little advanced sclerosis in the beginning of the aorta may therefore give rise to very serious consequences on account of consecutive, thrombotic, coronary occlusion; most frequently the right coronary artery is the one affected; but in two cases at any rate, namely Oestreich's and Chiari's, the left coronary artery has been closed by a secondary embolism.

The important fact to be learned from the case reported by Chiari is that rapidly developed complete occlusion of the main stem of the right coronary artery need not cause immediate death; the occlusion may be nearly or quite latent. Chiari thinks that in this case the occlusion occurred about two days before death, because at that time an abnormal condition of the pulse had been observed. The thrombosis had caused numerous foci of softening in the myocardium but the right ventricle had not been completely deprived of nourishment because it had carried on its usual function. Langer[5] showed by means of injection experiments that the two coronary arteries communicate with each other by branches that pass transversely across the anterior surface of the heart; furthermore that they anastomose through the vasa vasorum of the great vessels of the heart with the pericardial, the bronchial and even the diaphragmatic vessels. Hence the occlusion of the main trunk of one coronary artery does not deprive *the entire cor-*

responding vascular district of blood when the occlusion takes place gradually, as for instance, in case of uncomplicated sclerosis of the coronaries, then the collateral circulation may have time to develop to a considerable extent so that the disastrous consequences are in a measure warded off. The sudden occlusion of one or both main coronary trunks places greater demands upon the collateral circulation than can be met, and there may follow rather rapid suspension of the cardiac function. In Hammer's case the occlusion of the right coronay artery was followed by a condition of collapse that lasted thirty hours; the pulse was gradually reduced to eight beats in the minute; after the second sound came a distinct rumbling noise which Hammer connected with the shaking up the diseased part as the healthy half contracted. In Barth's case, which was not observed clinically, death followed after the patient had been feeling ill for several hours. In Oestreich's case the occlusion of the right coronary artery was probably not complete, and this partial thrombus undoubtedly existed for some time without any symptoms. In Chiari's case the symptoms during the time that only the opening of right coronary was closed consisted in some slowing of the pulse, which was slow and arhythmic, small and weak.

Lastly, it may be well to indicate that the results of the observations concerning the occlusion of a coronary trunk in the heart of man do not correspond exactly with the results of experiments on animals,[6] and to emphasize that great care should always be used in the application of the results of animal experiments to human pathology.

ATHLETICS IN RELATION TO HEALTH AND LONGEVITY.

Of all the things that enter into our tastes and aptitudes, but few excite more interest at present in the community at large than that of athletic sport. The thing itself, eminently Anglo-Saxon, is not among the tastes of the average French youth, who at the age of 16 usually takes to cigarettes, absinthe and a mistress, while most of our boys at college, keenly devoted to athletics and outdoor games, are incurring the fears of over-anxious parents as to the doubtful, if not deleterious, effect of this agency of modern education, concerning which many errors still prevail. One of the more current of these is that athletes are subject to organic disease and die young.

Regarding the three different educations that we receive, namely, that of the family, that from our school masters, and that of the world, the authorities own that mere book learning *in itself* is of little consequence in determining one's place in life, when compared with the inestimable value of good family antecedents and training and the worldly attrition with well-chosen associates. With no intention to undervalue the worth of study and sound scholarship, most of us may recall the honor men of our school days, who have turned out to be mere prigs and book worms, while those who stood nearer the foot of the list have been the successful ones to whom life's prizes have fallen. To be sure, books have their use, but as a rebuke to mere bookishness there seems to be much significance in the remark of the late Professor Henry of the Smithsonian Institution, regarding the agglomeration of medical books then in the Army Medical Museum, to the effect that it would be all the better for original research and the benefit of medicine, if some Calif Omar would apply the torch and wipe out the whole collection. Of course this wholesale denunciation of books, when viewed with judicial calmness, is merely an enlightened common sense protest against these dumb teachers, which do less for practical education than well-regulated acquaintance and intercourse with men.

Our species being eminently gregarious, there is from a socialistic point of view no branch of education more valuable than the fellowship arising from the community of thought and feeling that obtains in all collections of young people engaged in outdoor games or athletics. Notwithstanding the acknowledged good of such recreations by historians and philosophers since the days of Hippocrates, many popular fallacies yet prevail even among medical men, as to the effect of physical training and its bearing on health and longevity, and it would be difficult to equal the distortion of facts and temerity of language put forward in certain quarters in the howl against present day athleticism. Most of the published opinions that go to make up the popular notion relatively thereto, have emanated either from physicians having no practical acquaintance with athletics, or from sporting men who knew nothing of medicine.

Truth, as usual in such matters, lies between the two extremes. While a few exceptional cases break down and die young, it is now a well-ascertained fact that the beneficial effects of training and exercise tend to the benefit of the greater number by increasing health and longevity. The contention of this thesis was established in a paper embodying the experience of thirty years, read before the American Medical Association in Cincinnati, in which were cited many examples of athletes who lived to a hale and hearty old age.[1] The numerous macrobiotic instances therein cited are not open to the objection of being exceptional, since the writer's information and views have been supplemented by other observers in the same line, notably by John Boyle O'Reilly in his book about boxers; by the researches of Dr. J. Madison Taylor of Philadelphia (JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 1892, xviii, 705-710), who arrives at the same conclusions; by Dr. B. W. RICHARDSON of London, who, though disposed to condemn excessive athletics, concluded one of his last lectures at Oxford by saying that "good active sports and exercise in reason are amongst the clearest means of maintaining a long and happy life;" and last but not least, by the admirable essay of Sir MORRELL MACKENZIE, who ridiculed the sweeping statements that are still made from time to time as to the ruinous effects of exercise and training on the majority of those who find pleasure in the use and development of the strength with which nature has endowed them. In addition to the instances cited by these writers, others have appeared from time to time in the public prints. The former champion of the prize ring of England, JOHN GULLY, grandfather of the present speaker of the House of Commons, died at 80, and within the last few weeks the celebrated wrestler, MARSEILLE, whose prowess was witnessed years ago by many French grandfathers at country fairs, departed this life with the record of an octogenarian.

[1] Popular Fallacies Regarding Athletes and Athletic Exercises. Journ. Amer. Med. Assn., Apr. 27, 1889.

As an offset to the foregoing instances, we are often confronted with vague statements relating to the untimely death of several notables who have figured in the athletic world for the last twenty years or so; but in nearly every instance, as far as can be ascertained, the cause of break down was owing to immoderate indulgence, or the neglect of simple hygienic rules, resulting in such specific trouble as alcoholism, cirrhosis of the liver, or venereal disease. Dr. SARGENT of Harvard says from extensive personal knowledge he thinks the early demise of athletes directly attributable to free indulgence of gross appetites and passions and not to the result of athletic work.

We need only refer, in conclusion, to the accurate statistics collected by competent authorities, and to elaborate actuarial calculations, which demonstrate that oarsmen have in point of fact a longer expectation of life than others, and that the alleged baneful effects of boat racing are absurdly exaggerated. So prone, indeed, are the opponents of athletics to be blinded by prejudice, that these statistics have been abused even to the extent of quoting them as proof of the disastrous consequences, as we once heard a medical man do who, in citing the figures of Dr. MORGAN's accurate investigation, mentioned the "seventeen" victims, but said not a word about the remaining *two hundred and seventy-seven.* The mistake of mourning over one broken-down athlete and refusing to be comforted by the thought of a hundred others who were benefited by physical training, finds its counterpart in the denunciation of swimming by certain people who say that good swimmers are sometimes drowned, yet they totally ignore the hundreds who escape drowning from knowing how to swim.

Writing with the authority of experience and the maturity of observation, we therefore have forced upon us the induction that no good reason exists for the wholesale condemnation of athletism. On the contrary, it is evident that the healthy exercise of the physical powers is one of the necessary pastimes of a manly and vigorous race, and that next to food and sleep athletics has the largest share in the recreation of human life and in counteracting the tendencies of this hyper-neurotic age.

UNITED STATES COURTS VS. POST OFFICE AUTHORITIES ON ABORTIFACIENT NOSTRUMS.

There is a decided conflict between the United States courts and the United States post office as to the status of abortifacient nostrums. According to a recent decision in Judge SEAMAN's court, the United States Courts will enforce contracts for the sale of abortifacient remedies which are not permitted in the mails. The nostrum involved in the decision has been extensively advertised in the lay press as well as in the homeopathic journals as a "preventive of conception and a regulator of menstruation." In the case in which Judge SEAMAN's court rendered judgment the manufacturer of this nostrum was sued for violation of contract by a woman who had obtained certain territory in southern Indiana. She asserted that after she had worked up a good trade in this territory, the manufacturers filled orders in it without paying the commission, and her claim was based on this alleged fact. As the territory involved is largely a rural one, the dangers to the health of both mothers and children can not well be over-estimated. If the ordinary theory of law be correct, contracts to perform illegal acts such as the sale of this nostrum, are null and void. It can not be pleaded in the present instance that there is no evidence tending to show that the nostrum was of the character described. The United States post office authorities have already excluded it from the mails. It would therefore be no arrogation of authority for the United States district attorney to ask that the case be thrown out of court on the ground that the enforcement of the contract is against public welfare. As the Milwaukee Medical Society is in the court district and as the case will probably be appealed, that Society could render a great service to itself, to the local profession, to the profession and people of the United States, by inducing the local district attorney to do his duty. In this way the Milwaukee Medical Society could teach certain nostrum venders a very telling lesson.

CONCERNING THE EDITORIAL MANAGEMENT.

We clip the following from "A Journal of Reform and Progress in the Medical Sciences," under the head of "current comment." The truth is that every article connected with, or relating to the Ophthalmic Section that has appeared in the JOURNAL in the last three or four years, has been written by some member of the Section, and if our esteemed contemporary will re-read that "memorable diatribe" to which he refers, he will see there is nothing in it objectionable to the Section as a body, nor has anything of the kind ever appeared in the pages of the JOURNAL.

"There has been a revival of generous proportions in the editorial rooms of the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, and the Spirit has warmed the hearts of the special editorial writers since that memorable diatribe against the Ophthalmic Section of the National ASSOCIATION. The current issue of the JOURNAL goes out of its way to praise the Section quite as much as, a short time ago, it abused it. The JOURNAL has a large safety valve—praiseworthy editorials are by the editor, objectionable ones are by a special collaborator whose name it is not considered desirable to mention."

THE NEW SPELLING.

In answer to a valued contributor who objected to dropping the final "al" from the words physiologic*al* and biologic*al*, the Editor recently wrote:

"In regard to request for change of spelling I have to say that the JOURNAL long ago adopted the recommendation of the American Association for the Advancement of Science. However, your reprint will appear spelled as you wish. I quite sympathize with your feeling in the matter, but I suppose that our ancestors—some of them at least—raised a protest when the word 'arme' had the final 'e' dropped; the word 'legge' lost one 'g' and one 'e'; when the word 'thighe' lost its final 'e.' These happen to occur to me as I sit here, as specimens of how our language has grown by excision."

We print this because of other protests of the same character; in Vol. XXII, p. 25 will be found more specimens of the same sort.

CORRESPONDENCE.

The Section on the Practice of Medicine at the Late Meeting of the Association.

BUFFALO, N. Y., July 26, 1897.

To the Editor:—Your editorial in the JOURNAL of July 3, entitled "The Late Meeting of the Ophthalmic Section of the AMERICAN MEDICAL ASSOCIATION," must have attracted the attention of all your readers. The ASSOCIATION meeting was so notable in all respects that there may be danger of losing sight of the great excellence of the work in the various Sections.

It may not be out of place to emphasize once more the high estimate universally expressed of the work done in the Section on the Practice of Medicine. Knowing from experience how difficult it is to arrange a program satisfactory to all of a large body of physicians, the list of papers read and the discussions brought out are recalled not only with gratification but a certain amount of wonder.

It ought not to be necessary to reiterate the titles of papers nor to point out the wide range of subjects covered. It must be a satisfaction to remember that all parts of the country contributed and on adjournment the members separated with increased feelings of mutual respect. The suggestion is ventured that this program be preserved as a model for Dr. John H. Musser's successors in office. Very respectfully yours,

CHAS. G. STOCKTON, M.D.

PUBLIC HEALTH.

Thyroid Gland Extract as a Galactogogue.—The *Inter-colonial Medical Journal* of Australia contains, among other papers, an interesting communication by Dr. R. R. Stawell upon this subject. The value of a reliable medicine that would promote the secretion of milk would be immense, so that Dr. Stawell's results will have an interest for many practitioners. He details only nine cases, and, while admitting that this is but small clinical experience from which to generalise, concludes with some reservations that extract of thyroid gland is an efficient galactogogue. The dose given was from three to five tablets per diem. In view of Dr. Stawell's results we think that medical men are justified in giving the treatment a trial.

Detection of "Preservatives."—The use of preservatives in milk and butter has increased very largely during the last few years, in fact, during the summer months the practice of adding a preservative to milk may be said to be general. The preservative which finds most favor with the milk trade, is that known as "formalin," a more or less strong solution of formic aldehyde. Boric acid, borax, or a mixture of the two, are occasionally used for milk, and very largely for butter. From the public health point of view, this question of the addition of preservatives is most important. Whether or not such substances, in the quantities usually added to food, are injurious to health is still considered to be unsettled; but there can be no doubt that under the "Sale of Food Drugs Acts," the purchaser has a right to demand that the articles so doctored shall be labeled as containing a foreign ingredient. A very delicate method for detecting "formalin" in milk is O. Hehner's test, which consists in diluting the milk with its own volume of water, and carefully floating it over a little concentrated sulphuric acid, containing a few drops of ferric chlorid solution, contained in a test tube. In the presence of formalin a violet ring develops at the junction of the two liquids. This color is permanent for several days, if care be taken to prevent the tube being shaken. Carried out in this way one part of formalin can readily be detected in 200,000 parts of milk. In the absence of formalin, a brownish-red color develops, after some hours, not at the junction of the two liquids, but lower down in the acid.—*Public Health* (London), March.

Ptomain Poisoning by Pork.—Dr. Wynter Blyth reports, in the *London Sanitary Chronicle*, the cases of a boy and girl, aged respectively 11 and 5 years, who were brought to death's door by the ingestion of boiled pork, on a Saturday (March 27). Forty-eight hours later, the father, the boy and the girl were seized with choleraic symptoms, and at 2:30 on Monday afternoon the mother became similarly affected, but in a lesser degree. At 11 A.M. of that day, the boy and the girl had high temperature, the father choleraic symptoms, cramp, numbness of the feet and hands, and smarting of the eyes. The father, the mother, and the boy got better by about Tuesday, but the girl by Wednesday morning was almost pulseless, with cold extremities, and very nearly died. She, however, revived, and ultimately recovered. The pork was examined by the medical officer of health on April 1, on Wednesday, that is, four days after it was bought, three days after it had been boiled. At that date its appearance and odor were perfectly normal, but on passing it through a small sausage machine the finely divided fiber had a distinct stale smell. The pork was analyzed by Gautier's process, and ultimately a crystalline substance not in normal pork was separated. This substance was alkaline in reaction, gave fine crystals when united with hydrochloric acid, and precipitates with the ordinary alkaloidal reagents (save the chlorids of gold or platinum). So small a quantity was, however, obtained, that it was not practicable to examine it farther or to determine whether the substance was really a poisonous "ptomain," although this is naturally the inference. It may be suggested that the ptomain was in quantity in the meat on Sunday, and what the writer found was a small residue which had escaped destruction in the process of putrefaction.

Reforms for Hospitals and Reformatories.—The "Greater New York" has many unanticipated problems to solve, some of which belong to the semi-penal institutions, where poverty is a non-recognized crime. The New York State Board of Charities not long ago received a report on the condition of the Kings County Hospital, showing insufficient accommodations and not enough of restrictions in the admission of inmates. This hospital combines what in the city of New York itself would be divided up into the workhouse and almshouse, hospital and places for acute cases. It is astonishing, says the report, to find that any of the work is well done in this overcrowded, improperly equipped and ill-constructed hospital for the poor of one of the largest cities of the world. The Board has also received the report of the inspectors of the various reformatories in the State. The House of Refuge on Randall's Island is found in good condition and neatly kept. "We earnestly recommend," the report says, "the separation and the removal of the girls' department from that of the boys' in this institution. This evil in the development of our juvenile reformatory system is so patent and embarrassing that this committee urges positive and immediate action on the part of the Board to initiate this separation." The same recommendation is made in the case of the Rochester State Industrial School. Much serious comment is likewise made upon the reformatory system of the "Excelsior" State particularly in its dealings with juveniles, classed as first offenders. The Board holds that the present system is making more real criminals than it reforms. In the case of juveniles, male and female, especially under 16, commitments should be made directly to the reformatory as a guardian rather than as a penal institution. This course is followed in France, and none of the juveniles sent to reformatory or correctional institutions of that country are committed as convicted of a felony, but as a precautionary measure. The root of the evils in question is not so much with the hard-working officials and a hampered medical profession, but with so-called "statesmen" and pretended political economists. Public weal is one matter—appointments quite another. Between the trades unions and the tax-payers the honest humanitarians have but little consideration.

The Duality of Vital Statistics.—Vital statistics are as a barometer in which the sanitarian sees indexed the sanitary necessities of any locality, and traces its accordance or otherwise with those laws of health by which its death rate is either diminished or increased. Every one is aware of the *wonderful duality of statistics* and how they can be used and mixed by a skilful hand so as to furnish materials for any taste, and to prop up any shaky theory. Appealed to in evidence of conclusions thoroughly diverse, they often remind one of Meyrick's story of the chameleon, anent the description of which the two travelers so materially differed—the one asserting that its color was green, while the other swore it was blue. The umpire called in to decide pronounced it black as jet, and the beast itself, when produced, was found white as snow. So is it that statistics are appealed to for every purpose, and are often in the hands of party advocates or prejudiced opponents little better than a pack of cards in the hands of a skilful conjuror. Still, statistics can not be set aside or unduly underrated. Those vital statistics which it is the registrar's duty to collect are of such a nature as not to be capable of easy distortion. Each locality or district can separate them for itself, and learn those special lessons which they are fitted to convey. To show the practical use to which these statistics may be put, take the system originated many years ago in Leith, and now in force in Glasgow. The city is divided into a number of what might be called sanitary districts, each registrar supplies the sanitary authorities with a return showing every birth and death in each street; these figures are tabulated, and by a little comparison the undue mortality of any place within the districts is authoritatively ascertained, the causes of death enumerated, and other information bearing upon the health of the city indicated. Such a course is evidently approved by the framers of the new Public Health (Scotland) Bill, as there appears a clause providing that every registrar shall send a return of the deaths in his district to the medical officer of health, although the payment indicated in the bill is quite inadequate. However advantageous to the general work of sanitary reform may be the results of registration as embodied in the publications of the registrar-general, it must be evident that for local application they require to be more fully and minutely analyzed. Some physiognomists, it is said, derive their chief pleasure from the examination, not of the more prominent features of the human countenance, but of the minute lines, curves, and wrinkles such as escape the notice of the general observer Public money invested in the direction of obtaining these statistics is advantageously invested, and ought not therefore to be stingily applied. The public reap the benefit in that improved sanitary condition which throws a lifeguard round their homes, promotes their daily comfort, drains the prolific sources of disease, and robs the epidemic of its deadly strength. Public authorities may expend much labor and means in seeking to promote the social and sanitary well-being of their constituents, but without some intelligible basis from which to start, and some reliable data to direct, they can not be expected to attain commensurate results. Those who, from their position are qualified to aid them in their urgently important work ought to be dealt with in a spirit of liberality, indicating, on the one hand, their earnestness of purpose, and ensuring on the other hand, that the best thing being done in the best way will produce the best and most enduring results. Such an onerous and responsible position is held by every registrar in Scotland, and particularly by those called upon to act in the leading centers of population, but the recognition of this fact by local authorities is the exception and not the rule. Looking to the remuneration of other public officials who are not burdened with a tithe of the registrar's responsibilities, nor surrounded by any statutory civil and criminal penalties, it must be admitted that the provision made for registrars is most inadequate. Mr. John Archer in *Sanitary Journal* for April.

European Sanitaria for the Treatment of Tuberculosis.—Dr. Kaurin of Christiania, Norway, has published in *Lagevidenskaben* the results of his observations concerning the tuberculosis retreats on the continent. In Switzerland he visited Heiligenschwendi, in the Canton of Bern, 1,100 meters above the level of the sea. It is also surrounded by forests and faces toward the south. The climate here is more severe; in winter the thermometer descended to −37 degrees C., and in June the maximum temperature is +15 and minimum +7 degrees C. The treatment employed was hygienic-dietetic and was followed by good results. In the Canton of Graubunden he visited Davos, an Alpine valley, situated 1,500 meters above the level of the sea. The two small villages there are now yearly visited by more than thirteen thousand people having tuberculosis. The mean temperature is +2.6 degrees C., and the mean barometric measurement 631 mm. The snow covers the fields until May and +20 to +30 degrees C. is frequently recorded. From so severe a climate the patients return home much improved in health. In spite of the elevation, there seems not to be any disposition to hemoptysis; whereas it is contraindicated to send patients up there with developed anemia, neurasthenia, heart or laryngeal affections. Here in Davos there is a very peculiar institution, a school sanitarium for boys and girls sent by families disposed to tuberculosis, or with incipient phthisis. Boys and girls with poor health are sent up there also, and healthy children from the neighborhood frequent the same school. From Switzerland the author visited some places farther north in Sudeter Mountains and praises Gobersdorf, which is situated 560 meters above the level of the sea. Here, as in Davos, the patients with fever are kept out in the fresh air, and with good effect. Here, also, as in other places, 24 per cent. are cured. In the suburbs of Berlin he visited the barracks of Doeckert, situated in a large pine grove and given up to the Red Cross Society, for the benefit of tuberculous people. The cost per day is three marks per capita. Here, as well as in Malchow and Blankenfeldt, are two hospitals for tuberculous patients from Berlin hospitals, and situated on the plains irrigated by the Berlin sewers. The result is very satisfactory. In Malchow and Blankenfeldt the cost per day is only two marks and the treatment does not last more than forty-four days. Even if not cured in this short time the patients go back to their homes in the city improved in health and trained to a better mode of living. The celebrated establishment at Falkenstein in Nassau, of which Dr. Dettweiler is the director, is situated 400 meters above the level of the sea, surrounded by extensive forests on the southern slope of Taunus Heights. Not far away is Ruppertshain, a sanitarium for a poorer class of people, costing from two and a half to five marks a day. The climate is dry and a little windy, with a good deal of rain in spring and fall; in the winter the thermometer falls below the freezing point, generally to 8 or 10 degrees Celsius, and a little snow falls. The temperature changes slowly. The buildings are three stories, with corridors for patients on the front—open but protected with canvas against rain and direct sunshine. The regular treatment, lasting three months only, is based on the Bremer-Dettweiler method, the open-air treatment, the treatment in the corridors, and abundant nourishment, with regular exercise to strengthen the heart, and the disinfection of the sputa. Medicine is not much used; mostly to relieve symptoms. The result is very satisfactory, the percentage of cured being 24 (13 per cent. entirely cured and 11 per cent. able to resume work). Of 99 cured, 72 remained well for three to nine years after treatment, 15 had a relapse, and of those 12 were again cured after a renewal of the treatment. The little village, Falkenstein, close by, with 800 inhabitants, seems not to suffer from this so-much dreaded neighborhood, inasmuch as the death rate from tuberculosis here is less now than formerly.

BOOK NOTICES.

The Menopause; a Consideration of the Phenomena which Occur to Women at the Close of the Child-bearing Period, with Incidental Allusions to their Relationship to Menstruation; also a Particular Consideration of the Premature (especially the Artificial) Menopause. By Andrew F. Currier, M.D. Cl. 8vo. pp. 309. New York: D. Appleton & Co., 1897. From A. C. McClurg & Co., Chicago.

This book is not only entertaining from a literary standpoint, but it is meritorious from a professional point of view.

The author's chapter on the artificial menopause is interesting, but rather disappointing. Surely there must be sufficient experience in the after-effects of ovarian and tubal extirpations, to say nothing of hysterectomies, to have made more definite statements and more extensive observations. One must admit the truth of what the author says, but there is much more to be gathered.

The general trend of the book is to combat the view that the period of the menopause is a period fraught with danger. On the contrary, that period should be considered as a physiologic process and be passed with as little pathologic sequence as the menstrual period came on. The book is on a very practical topic and we are sure it will be well received.

A Short Practice of Midwifery, Embodying the Treatment Adopted in the Rotunda Hospital, Dublin. By Henry Jellett, B.A., M.D., etc., with a preface by W. J. Smyly, M.D., late Master of the Rotunda Hospital. With forty-five illustrations and an appendix containing the statistics of the Hospital for the last seven years. pp. 323. Philadelphia. 1897. Price $1.75.

This little volume will prove acceptable not only to those who desire a brief account of the practice of the great Rotunda Hospital, but to those interested in keeping pace with the progress of modern midwifery. Aseptic methods are taught and we regard the work as an excellent epitome and well worth careful study by students everywhere.

Crime and Criminals. By J. Sanderson Christison, M.D. Chicago: *The W. T. Keener Co. 1897.*

This is very evidently not a systematic treatise on criminology, as the author admits. It is only some brief sketches, mostly of a few not uncommon or specially prominent types of criminal defectives. It is popularly rather than scientifically written, and the author states in his preface that the work is largely a reproduction of newspaper articles which, it would appear from his preface, have aroused attention both in Europe and America. He has therefore collected them and published them, with some additions, in book form for the benefit of the public.

While the style of the book is generally readable, the author would have done well had he revised it more carefully in some parts. The publishers have done their work well; the make-up, illustrations, etc., are very good.

ASSOCIATION NEWS.

Committee on Transportation.—*To the Editor:*—The committee on rates to Denver in 1898 has been appointed by President Sternberg as follows: Dr. W. H. Daly, Pittsburg, Pa., chairman; Wm. Pepper, Philadelphia, Pa.; X. C. Scott, Cleveland, Ohio; J. D. Griffith, Kansas City, Mo.; C. M. Drake, Atlanta, Ga.; L. H. Montgomery, Chicago, Ill.; H. O. Marcy, Boston, Mass.; J. W. Graham, Denver, Colo. The President says: Dr. Daly writes me that the committee is already industriously at work and that a rate of one-half and thirty days time seems to be the certain outcome of their labors."

Yours very truly,
W. B. Atkinson, M.D.

Section on Ophthalmology.—Members of the Section on Ophthalmology, and others interested, who have not already subscribed for the bound volume of the proceedings of that Section for 1897, may obtain a copy when issued by sending name and addres and $1 to the Journal office, or to Horace M. Starkey, 70 State St., Chicago. These orders should be sent in within the next two weeks.

SOCIETY NEWS.

Indian Territory Medical Association.—At the regular semi-annual meeting of the Indian Territory Medical Association held at South McAlester, I. T., June 29 and 30, 1897, the following officers were elected for the ensuing year: President, E. N. Allen, M.D., South McAlester; first vice-president, G. W. West, M.D. Eufala; second vice president, J. B. Roleter, M.D., Oklahoma City; secretary, LeRoy Long, M.D., Caddo.

New Jersey Medical Examiners.—The annual meeting of the State Board of Medical Examiners of New Jersey was held at Jersey City, Monday, July 5. Dr. George F. Wilbur of As-bury Park, was elected president; Dr. E. L. B. Godfrey of Camden, secretary, and Dr. A. Uebelacker of Morristown, treasurer. There were sixty-eight candidates who reported for the June examination, of whom 12 per cent. were rejected.

French Congress of Surgery, to be held at Paris, October 18, will discuss the questions of "Contusions of the Abdomen" and "Indications for an Operation and Treatment of Cancer of the Rectum." Sec. L. Picque, Rue de l'Isly 8, Paris.

Twelfth International Medical Congress.—*To the Editor:* –In a letter dated July 7 Dr. H. Kümmell, surgical director of the New General Hospital (Neues Allgemeines Krankenhaus) of Hamburg, in the names both of the local Hamburg and the General Imperial Committees of the Twelfth International Congress, begs to invite American Congressists to inspect the hospital and the new hygienic establishments. The medical men will be at the hospital daily from 10 A.M. to 2 P.M.; still they request American Congressists to kindly notify them, if possible, of the days of their intended visits. Very respectfully.

New York, July 19, 1897. A. JACOBI.

Mississippi Valley Medical Association.—Meeting at Louisville Oct. 5, 6, 7, 8, 1897. The Executive Committee met recently at Louisville, in conjunction with the local Committee of Arrangements, the following being present: Drs. Stucky, Grant, Mathews, Love, Holloway and Reynolds. It was determined to make the coming meeting the largest and best in the history of the Association, and everything points to a fulfillment of this endeavor. The railroads will make a round-trip rate of one and a third fare, or probably one fare. The address on surgery will be delivered by Dr. J. B. Murphy, Chicago; the address on medicine by Dr. John V. Shoemaker, Philadelphia. Title of papers should be sent to Dr. H. W. Loeb, Secretary, St. Louis, Mo.

The Neuron at the German Congress of Internal Medicine.—Goldscheider remarked in his address that we assume now that each neuron with its axis cylinder and dendrites is a functional and nutritive unit, communicating by contact alone with the rest, but if a sufficiently powerful stimulus is applied, it will be transmitted like a wave, entirely around the whole of the central nervous system, preferably following the routes offering the least resistance. Each neuron has an individual standard of excitability—a limit that must be passed before it shows the effect of the excitation. This limit varies under different conditions. Slight excitation increases the excitability of the neurons, but violent excitation decreases it and is followed by hypo-esthesia of a whole region. Such a condition exists in hysteria, while on the other hand, neuralgia and the tachycardia accompanying neuralgia, produce a hyperexcitability. The same stimulus in these conditions produces a much more intense excitation than in normal. Psychic conditions also affect it. These variations in the standard of excitability of the neurons must be borne in mind in organic diseases of the nervous system, in which the lesion does not account for all the phenomena observed. In tabes, for instance, we do not know whether the lightning pains precede the establishment of the lesion, or whether the subjective troubles are caused by it. Substitutions and compensations are accomplished by an increase in the faculties of hitherto inactive neurons. We know that stimulation of certain portions of the skin will affect the viscera, showing a connection between the cutaneous sensory neurons and the sympathetic neurons. The effect on the brain during sleep, of the stomach and intestine loaded with food, can be compared to the effects of cutaneous pruritus. Therapeutics must not be restricted to remedy the anemia or hyperemia of the nervous elements, but also aim to affect the irritability of the neurons. In case of hyperalgesia of one member, for example, the pain can be reduced by acting upon the neurons of the symmetric member; electrization, for instance, will increase the excitability of the neurons, while massage and hydrotherapy may divert and thus reduce it. These measures open or close the road to excitation. The stimulus of cold or hot baths removes the sensation of fatigue. Various measures can be used to assist the will, too weak to determine alone a motor action. Suggestion, for instance, which can be considered an excitant of the neurons. Thermic influences also have an incontestable effect on the vasomotor and trophic neurons. Even in certain degenerative processes dynamic action on the neurons may have a useful therapeutic effect. The assumption of a dilation or contraction of the blood vessels is not an adequate explanation of the effects of thermic stimulation. The entire nerve substance is affected in a certain measure by its exciting effect on the trophic neurons. He advocated in conclusion "dietetics of the neurons" as more effectual than all pharmaceutic means in progressive degenerative conditions of the nervous system. M. Sternberg of Vienna added that the standard of excitability in the individual neuron (the *Neuronschwelle*), is the result of the equilibrium between the force applied and the resistance, and is therefore necessarily variable. "We have been concentrating our attention on the study of degenerative processes in the nerves, but in nature everything is not always either *black* or *white*. There are intermediate stages, which have not yet been sufficiently studied."

NECROLOGY.

JAMES S. WHITMIRE, Metamora, Ill., who died July 15 (*vide* JOURNAL, p. 200) received the degree of M.D. from the Medical Department of Illinois College in 1847. He afterward studied in Rush Medical College and while there was awarded the first *ad eundem* degree ever conferred by that college, his thesis embodying investigations made by him concerning iodin as an antidote to rattlesnake venom. In 1856 he also received the degree of M.D. from Jefferson Medical College. As surgeon of the Fifty-sixth Illinois Volunteer Infantry, with rank of Major, he participated in the battles of Iuka, Miss., and of Corinth, and after the latter had the reputation of performing the only successful hip operation (performed on a Confederate soldier) that had been done in the Western Department up to that time. Dr. Whitmire was the first to use a 6 per cent. solution of carbolic acid as a subcutaneous injection in erysipelas. (Reprint from "Physicians and Surgeons of America.") He had been a member of the Illinois State Medical Society since 1850; helped organize the Woodford County Medical Society; and was a member of the N. C. Illinois Medical Association and the AMERICAN MEDICAL ASSOCIATION.

DELOS A. CRANE, M.D., at Holland Patent, N. Y., July 22, aged 76 years. He was a graduate of Castleton Medical College, Vermont, class of 1841; was well known in Oneida County, and up to his death was a special Pension Examiner from the date of his appointment in 1865.

WILLIAM H. MCNAUGHTON, M.D., for two years Health Officer of Watervliet, N. Y., July 22, from consumption, aged 34 years.

EDWARD M. HIGGINS, M.D., Hot Springs, Ark., July 18, from apoplexy, aged 43 years. He received his medical degree in 1877 from Queen's University, Kingston, Ontario, of which city his father is a resident, and there Dr. Higgins was spending his vacation.

WILLIAM C. WEST, M.D., Geneseo, Ill., died at his home July 10, 1897, of suppurative pancreatitis. Dr. West was born in Maryland Feb. 27, 1835, and had been an active practitioner for thirty-four years, having been graduated from the College of Physicians and Surgeons of Keokuk, Iowa, 1863. He was a member of the AMERICAN MEDICAL ASSOCIATION, of the Illinois State Medical Society, and for a number of years a leading member of the American Microscopical Society. His remains were taken to Monroe, Mich., for burial.

RESOLUTIONS ON THE DEATH OF DR. B[illegible].—At a regular meeting of the Alumni Association of the University Medical

College, Kansas City, Mo., held on Monday, July 12, 1897, the following resolutions were unanimously adopted:

WHEREAS, it has pleased the Almighty Providence to remove from among us by the act of a cowardly assassin, our honored and beloved friend and teacher, Dr. Lyman A. Berger, be it

Resolved, That his untimely death in the prime of professional life and usefulness, fills our hearts with deepest sorrow, and has created a lamentable vacancy in our faculty.

Resolved, That in the demise of Dr. Lyman A. Berger our profession has lost a trusted member and a zealous and valued colleague, and our Alma Mater a faithful and kind hearted friend.

Resolved, That his efforts in behalf of medical education in materially advancing the progress of the University Medical College are greatly appreciated; and as the founder and patron of its obstetrical clinic he has permanently contributed to its usefulness and earned the lasting gratitude of not only our Association and the medical profession, but of the community at large.

Resolved, That we fervently sympathize with the grief-stricken family, who have lost an exemplary husband, a devoted father and a true physician.

Resolved, That the foregoing resolutions be spread on our minutes, a copy thereof be sent to the bereaved family of the deceased, and the same be published in the daily papers of our city, the local medical periodicals and the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION.

B. ALBERT LIEBERMAN, M.D., Chairman,
A. L. HUNT, M.D.,
B. L. SULZBACHER, M.D., Committee.

ROBERT HUBBARD, M.D., Bridgeport, Conn., July 18, aged 76 years. In 1862 he was commissioned surgeon of the Seventeenth Regiment Connecticut Volunteers. After a few months' service he was promoted to surgeon of brigade under General Howard. For meritorious conduct at the battle of Chancellorsville, Dr. Hubbard was promoted to be medical inspector —assistant medical director—on the staff of General Devens. At the battle of Gettysburg, he served as medical director in charge of the Eleventh Corps. When the Eleventh Corps was ordered to Lookout Mountain he again served as medical director under General Hooker, and in that capacity took part in the battles of Lookout Mountain, Missionary Ridge and Ringgold.

MATTHEW P. LYON, M.D., died at Camden, Wash., May 18, aged 79 years. He crossed the plains to California in 1849, and has resided in Washington since 1878.

JOHN N. BEACH, M.D., West Jefferson, Ohio, July 17.——Henry C.
Paschal Davis, M.D., Keokuk, Iowa, July 16.——Tyler Hull, M.D.,
Hinkle, M.D., Oakland, Cal., July 13.——Alfred
Dimondale, Mich., July 17, from blood poisoning.——Alfred
Marshall Mayer, M.D., July 13, aged 66 years, and for the past
twenty-one years professor of physics at the Stevens' Institute
of Technology, Hoboken, N. J.——Selden W. Noyes, M.D.,
Higganum, Conn., July 12, aged 51 years.——P. L. Garvey,
M.D., Oakland, Ill., July 11.——Prof. D. Hofer, Munich.——
A. Nocquart, Brussels, professor of path. anat., from infection
at a necropsy.——Schutzenberger, professor of chemistry at
the Collège de France.——Legros, professor of phys. at Brussels.——G. Fissore, professor of med. path., Turin.——T. de
Carvalho, professor emeritus of surgery, Lisbon.——Cernea,
professor of int. path. at Jassy.

MISCELLANY.

Personal.—Dr. Frederick Holme Wiggin has been appointed a delegate from the New York State Medical Association to the British Medical Association meeting at Montreal.

Dr. W. W. Potter has been reappointed health officer of Spokane, Washington.

A Medical Lending Library has been recently opened in connection with M. Boas' medical book store in Berlin, which circulates valuable antiques as well as the most modern works.

A Museum of Hygienic and Sanitary Appliances, with a library of appropriate literature and a hall for addresses on this subject, has just been opened in Moscow.

The Professional Fifty-year Jubilees of V. Koelliker and Professor Lefebvre have just been celebrated with affectionate zeal by their friends at Wurzburg and Louvain, respectively. The former is 80.

Women to be Admitted.—It is understood that hereafter women will be admitted as students into the medical classes of the College of Physicians and Surgeons of Chicago.

Extirpation of Struma in Hypnosis.—The operation lasted forty-five minutes; no pain was felt and the patient recovered in nine days. She was a woman of 38, especially susceptible to hypnotic suggestion, which had previously relieved her of neuro-rheumatic pains several times.—*Cbl. f. Chir.*, June 26.

Chain Instead of Weights for Precision Scales.—The inconveniences of the tiny weights required for delicate scales have been obviated by the substitution of a chain fastened to the beam, graduated, and moved by a lever from outside the case. The chain is arranged so that weights can be used as usual when desired. Serrin, in *Nouveaux Remèdes*, June 24.

Monument Erected to Duchenne of Boulogne.—A portrait medallion of the great neuro-pathologist was uncovered with appropriate ceremonies recently in Paris, inserted in the wall of the pavilion that bears his name in the Hospital de la Salpetrière. The bas relief below represents Duchenne applying the electrodes of an inductive machine on a patient, with the inscription: "Duchenne de Boulogne, 1806–1875, Electrisation localisée. Physiologie des mouvements. Neuropathologie."

Excision of an Extensive Lupus with Skin Grafting.—Matagne describes in the *Gaz. Méd. de Liége*, June 17, his operation to relieve a girl of 16 of a lupus, 12 by 9 centimeters on the arm, which had developed fourteen years before, after vaccination with vaccine from another person. He tested the patient with tuberculin before attempting to operate, and completed the excision with transplantation of skin from the thigh. Five years have passed since without a relapse and the patient seems absolutely cured.

Production of Light by Living Creatures.—Dubois confirms authoritatively his recent announcement that the light produced by the pholas dactylus is caused by the combination of an enzyme insoluble in alcohol, soluble in water and destroyed by heat (luciferase), with a substance soluble in alcohol (luciferin). Both of these substances are found associated in the walls of the respiratory passages of the pholas, and can be extracted from the tissues by alcohol and water in turn. By combining the alcohol solution of luciferin and the aqueous solution of luciferase with plenty of oxygen the light is produced.—*Cbl. f. Phys.*, May 1.

Three Laparotomies on One Patient for Sarcoma of the Adnexa.—Five years after a septic adnexitis consecutive to a criminal abortion, a malignant sarcoma developed in a pyosalpinx; extirpation. One year later the sarcoma grew again in the adnexa and abdominal wound; extirpation, with slight injury to the intestine. Again the sarcoma developed in the intestinal wound, but extirpation this time was soon followed by the death of the patient. The necropsy showed fatty degeneration of the internal organs. There had been nc metastasis of the malignant growth, which had been thus successfully fought for nine years.—*Cbl. f. Chir.*, June 26, from *Lieeknicki viestnik*, No. 3, 1896.

National Charities Conference at Toronto, Canada, held early in July, was a symposium of excellent ideas, despite certain bureaucratic tendencies. Necessarily morals rather than sanitation or dispensary abuses claimed most of the attention of the readers and speakers. The veteran received a large share of attention during a morning session, and "Homes" were discussed in their practical phases and limitations. "Practical Charity and Jewish Methods" was the suggestive title of one paper, and the "Value of Investigation and Dangers Incident to it" was that of another. Children were well cared for, as may be gathered from the subjects of the essays, an example being afforded by the address of William P. Letchworth of the State Board of Charities, New York, which was entitled "Dependent Children and Family Homes." We trust above all that pride of opinion did not mar the amenities of debate, and that clamor did not interfere with the enjoyments of reform.

"About Children" is announced by the *Medical Gazette* Publishing Company. The author is Dr. Samuel W. Kelley, Professor of Diseases of Children in the Cleveland College of Physicians and Surgeons, the editor of the *Gazette.* Advance orders will be filled in September.

The Mission Hospital at Sitka, Alaska, is doing splendid work. The building contains ten rooms and two large wards. It is in charge of a resident physician who lives in a cottage on the grounds. The matron and head nurse is a graduate of the Buffalo Hospital Training School. She has four native girls in the training school. The hospital was built for the care and the treatment of the children of the mission, but natives and even whites are admitted in emergency cases. During last year nearly 200 were treated in hospital and 1,160 were given dispensary relief; 93 surgical operations were performed.

The Birth Rates of France and America.—The lay press seems to be in the throes of a hot canvass over the relative morality of France and America, so far as suppression of their relative population is concerned. The *Chicago Inter-Ocean* furnishes the following summary: "While in France the birth rate is 22 per 1,000, in Nevada it is 16.30 per 1,000; in Maine, 17.99 per 1,000; New Hampshire, 18.4 per 1,000; Vermont, 18.5; California, 19.4; Connecticut, 21.3; Massachusetts, 21.5; Rhode Island has 22.5 per 1,000, a little more than France; Wyoming has 21.8 per 1,000, and Oregon 22.5. If it were not for immigration, the population would be gradually falling off, and according to statistics the inhabitants of New England and the Pacific coast will be replaced by another race within a period varying from sixteen to 200 years."

Koch's New Tuberculin. — Nencki, Maczewski and Logucki (*Presse médicale*, No. 46) publish some critical remarks on the new preparation of Koch, which merit the attention of the profession. Nencki observed while trying the new tuberculin on a patient, after every injection a considerable reaction with general indisposition, chills, fever, etc. Examining the tuberculin which he used for the injections he found it containing numerous pneumococci, staphylococci and streptococci. Two other bottles which he opened with every aseptic precaution contained the same bacteria. Inoculated on sterile nutrient media they grew very well. It seemed very probable that during the manufacture of the product, as published by Koch, a contamination could easily occur. In spite of this Koch does not believe that an improvement of his method can be thought of. It is evident that such contaminations can lead to considerable danger for the patient, and it will be necessary that the manufacturers furnish sufficient guarantees for absolute purity of their products by a severe and reliable control, before they can be generally tried as to their efficacy.

Population of Russia.—The St. Petersburg correspondent of the *New York Times* under date of June 10 writes: "The published reports of the Russian census, taken last January, are interesting from many points of view. According to the results now known, the population of the whole Russian Empire is a little less than 130,000,000. This is without counting certain provinces of Caucasia and Turkestan and the inhabitants of Northern Siberia, the exact figures of which have not yet reached St. Petersburg. St. Petersburg has 1,267,000 inhabitants; Moscow a little less than a million without the suburbs. The most interesting figures of the census are those concerning Warsaw and Odessa. The Polish capital, which in the days of Polish independence had less than 50,000 people, now has a population of 615,000 souls. Odessa's rapid growth is even more remarkable, for a century ago it was nothing but a poor fishing village, and it now has over 400,000 inhabitants. The towns of Riga, Lodz, Tiflis and Astrakhan have likewise increased in a remarkable manner.

Tricks on the Charitable.—The New York State Board of Charities in reporting on the modes of placing out dependent children, states substantially that "the worst of these is by an individual claiming to represent the 'National Children's Home Society' of Chicago, under a charter granted by Illinois to the 'American Educational Aid Association.' Some three years since he applied for an incorporation of a branch of the society, which was refused. In spite of the failure to obtain approval, he has continued to solicit funds and place out children. He has been responsible, apparently, to no supervising authority for the funds which he has secured from the benevolent. As high as 40 per cent. of the subscriptions raised by this soliciting agent was by agreement retained by him."

Higher Medical Education.—The *Alchemist and Neurologist* (April, 1897) waxes wroth over "State medical detectors called examining boards" and refers to "a new proposition to examine the professors." The *reductio ad absurdum* is rather pertinently put by the question, "but if the faculties are to be examined by a board of examiners who will examine the examiners and attest their qualifications?" We agree in spirit with the paragraph that "defamation of American medical colleges by little mediocrities in medicine has about reached the limit of toleration by the friends of medical education in the profession." To this we may add the truism that critics are seldom originating geniuses.

More Rigor in Medical Examinations.—The Massachusetts medical practice act has been made more rigorous in operation by the decision of the State Board of Registration in Medicine to increase the requirements at examination. Formerly the graduates of medical schools were asked only two questions under each of five topics and the non-graduates five. Now all are required to be examined on ten, and they must average 70 per cent. on the total in order to pass. In recent examinations about 25 per cent. of the applicants have been rejected, and the proportion may be increased by the added restrictions. There will be no dearth, however, in the supply of doctors. At an examination this week the candidates numbered 225, and 21 of them were women. Under the operation of the law there has been, it is said, a distinct elevation of the practical ability and moral quality of the medical profession. It has resulted, also, in a marked improvement in some of the medical schools, which have stiffened their requirements.

Chronic Abscess of the Brain, with Rupture into the Frontal Sinus.—Zamazal (*Wien. medizinische Presse*, June 26, 1897, p. 1190) has reported the case of a man, who complained of pain in the left frontal region, with intermissions and exacerbations. The left upper eyelid was the seat of a large cicatrix, resulting from a blow received eight years previously. The patient was lost to observation for nearly two years, when he returned on account of copious epistaxis. Other than the existence of albuminuria and enlargement of the left ventricle, with a slight peculiarity in speech and signs of mild mental perturbation, no abnormality was noted. Despite measures directed to the control of the epistaxis the bleeding was repeated, the symptoms grew gradually more pronounced, coma set in after the discharge of a considerable quantity of blood and pus from the nose, and death followed. Though no reference to post mortem examination is made, the opinion is expressed that in consequence of the traumatism an abscess developed in the left cerebral hemisphere, rupturing after a long period of latency into the frontal sinus.

A Fifty-four Year Medical Course.—A medical student has just graduated in Warsaw, 75 years old. He commenced his course in 1843, but was forced to suspend it for lack of funds, and became a teacher for twenty years before he was able to return and resume it. He then partially completed the course when he became involved in the political uprising in Poland in 1863, and was sent to Siberia, where he worked in the mines for thirty-two years, when he was pardoned and returned to Warsaw to graduate at last.

The Old Pharmacopeia to be Used.—The supreme court of Ohio holds, in the case of State v. Emery, Dec. 1, 1896, that the reference, in Section 3 of the pure drug statute (87 Ohio Laws, 248), to the United States Pharmacopeia, is to the edition in general use when the statute was enacted, which was that of 1880. The sale of a drug, which was equal to the standard of strength, quality and purity laid down in that edition, it continues, is not rendered unlawful because it is below a higher standard laid down in a subsequently revised edition, though that edition was in general use when the sale was made. And a copy of the subsequent revised edition is not competent evidence on the trial of a prosecution under the statue. The reason given for this decision is that it is not to be supposed that the legislature intended to adopt, by reference, as part of the penal laws of the State, an edition not then in existence, and of which the legislature could then have no knowledge, and that to hold otherwise would be equivalent to holding that the revisers of the book could create and define the offense—a power which belongs to the legislative body, and can not be delegated.

Cyclotherapeutics.—M. Siegfried (Berlin, Nauhaim) has derived great benefit in certain cases from specially constructed tricycles with adjustable seats, pedals and cushions and made comfortable, and ordered as the therapeutic measure under the strict supervision of the physician, never allowing it as a sport to be indulged in at will. He describes in the *D. Med. Woch.* of July 1 the remarkable results attained in a few specimen cases of heart and spinal troubles, gout and relapsing polyarthritis, rheumatics with ankylosis of the joints and atrophy of the muscles. Patients confined for years to invalid chairs are restored to life and activity, attend to their business and take a daily tricycle ride alone. The cyclotherapeutic treatment is often extremely painful at first and is commenced very gradually, with baths, etc., with frequent intermissions. The special tricycles for this purpose are manufactured by the Adler bicycle works of Frankfurt-a.-Main.

Seal Upon Physician's Lips no Shield for Unlawful Acts.—In the case of Hauk v. State, where the supreme court of Indiana affirmed a conviction of producing an abortion, the court holds, Feb. 16, 1897, that the rule declared by the statute, which for- bids a physician to reveal in evidence matters discovered by him in the course of professional attendance or treatment of a patient, is intended to protect the latter and not to shield one who is charged with perpetrating an unlawful act upon the patient. The statute, it insists, can not be so construed as to permit a party charged with crime to invoke it as a weapon of defense in his own favor instead of its being used as a protection to his victim. This interpretation, in its opinion, accords with reason and is supported by authority. On these grounds the court holds that it was not error to permit the physician who attended the patient in question, at the request of the defend- ant, at the time of her alleged miscarriage, to give evidence of what he discovered upon an examination of his patient during his attendance, and also the fact that the miscarriage occurred while he was present as her physician. The fact that her death may have resulted from the improper treatment of her physician or otherwise, it further holds, would not operate to defeat the conviction, under the statute, of the one who pro- duecd her miscarriage by an unlawful antecedent act.

Gleanings.—Extractum secale cornutum found a specific for diabetes insipidus in two cases by M. Benedikt. Dose: 3 grams in fifteen doses for five days. . . . Case of chronic diphtheria complicating erysipelas, resisting serum treatment, in observation four months (Jessen). . . . Perforating peritonitis from gastric ulcer, treated by absolute deprival of food and drink by mouth or rectum; large doses of opium and two to three injections a day of salt solution, 300 to 500 c.c., which prevented thirst and kept the circulation normal. Complete recovery (Lenhartz), *D. Med. Woch.*, July 1. . . . Pulmonary lithiasis in girl of 19, twenty calculi, largest weighed 2 centigrams. *J. de M. de Paris*, June 27. . . . Felix Semon, the German laryngologist in London, created a baronet during the Jubilee. . . . To supply air to cultures of the Koch bacillus to promote growth, Lucatello starts the colony on a strip of gauze suspended in a 2 liter jar, with the lower end touching the glycerined bouillon. . . . Experiments with ovarian juice in twenty-five cases showed no effect except upon the nervous system, which was excited, especially the sexual sphere. *Gaz. degli Osp. e delle Clin.*, June 20. . . . Virulent pathogenic germs of anthrax found in the feces of immunized animals. *Gaz. degli Osp. e delle Clin.*, June 17. . . . Success of the permanent sound and deambulation in troubles caused by hypertrophied prostate (Bazy). As efficient as surgical intervention. . . . New sign of tricuspid insufficiency, a pulsation in the second intercostal space, near the left edge of the sternum. *Presse Méd.*, June 12. . . . Violent fever, hypertrophied spleen, etc., lasting a week, with albuminuria, caused by a twenty-nine hour bicycle ride. Another case had a four week typhic fever after riding 45 kilometers, with phlebitis, myositis and myocarditis. Both typical auto-intoxication from over-exertion. *Presse Méd.*, June 12.

Study of the American Medicinal Flora.—The Sub-commission of the Pan-American Medical Congress appointed to study the medicinal plants of the United States has entered into an association with the Smithsonian Institution for that purpose. The attention of our readers is called to the respective circulars issued by these organizations as follows:

"The Smithsonian Institution has undertaken to bring together all possible material bearing on the medicinal uses of plants in the United States. Arrangements have been made with a body representing the Pan-American Medical Congress, the Sub-commission on Medicinal Flora of the United States, to elaborate a report on this subject, and the material when received will be turned over to them for investigation. The accompanying detailed instructions relative to specimens and notes have been prepared by the Sub-commission. All pack- ages and correspondence should be addressed to the Smithsonian Institution, Washington, D. C., and marked on the outside '*Medicinal Plants for the U. S. National Museum.*' Franks which will carry specimens, when of suitable size, together with descriptions and notes, free of postage through the mails, will be forwarded upon application. Should an object be too large for transmission by mail the sender is requested, before ship- ping it, to notify the Institution, in order that a proper author- ization for its shipment may be made out.

[Signed] S. P. Langley, Secretary."

Instructions Relative to Medicinal Plants.—The Pan-American Medical Congress, at its meeting held in the City of Mexico in November 1896, took steps to institute a systematic study of the American medicinal flora, through the medium of a general commission and of special Sub-commissions, the latter to be organized in the several countries. The Sub-commission for the United States has been formed and consists of Dr. Val- ery Havard, U. S. A., Chairman; Mr. Frederick V. Coville, Botanist of the U. S. Department of Agriculture; Dr. C. F. Millspaugh, Curator of the Botanical Department of the Field Columbian Museum, Chicago; Dr. Charles Mohr, State Botan- ist of Alabama; Dr. W. P. Wilson, Director of the Philadel- phia Commercial Museums; and Prof. H. H. Rusby of the New York College of Pharmacy. This Sub-commission solicits in- formation concerning the medicinal plants of the United States from every one in a position to accord it. The principal points of study are as follows:

1. Local names.
2. Local uses, together with historical facts.
3. Geographical distribution and degree of abundance in the wild state.
4. Is the plant collected for market, and if so, *a.* At what season of the year? *b.* To how great an extent? *c.* How pre- pared for market? *d.* What is the effect of such collection upon

the wild supply? *e.* What price does it bring? *f.* Is the industry profitable?.

5. Is the plant, or has it ever been, cultivated and if so give all information on the subject, particularly as to whether such supplies are of superior quality, and whether the industry has proved profitable.

6. If not cultivated, present facts concerning the life history of the plant which might aid in determining methods of cultivation.

7. Is the drug subjected to substitution or adulteration, and if so, give information as to the plants used for this purpose.

While it is not expected that many persons will be able to contribute information on all these points concerning any plant, it is hoped that a large number of persons will be willing to communicate such partial knowledge as they possess. It is not the important or standard drugs alone concerning which information is sought. The Sub-commission desires to compile a complete list of the plants which have been used medicinally, however trivial such use may be. It also desires to collect all obtainable information, historical, scientific and economic, concerning our native and naturalized plants of this class, and, to that end, invites the coöperation of all persons interested. Poisonous plants of all kinds come within the scope of our inquiry, whether producing dangerous symptoms in man, or simply skin inflammation, or, as "loco-weeds," deleterious to horses, cattle and sheep. In this respect, the general reputation of a plant is not so much desired as the particulars of cases of poisoning actually seen, or heard from reliable observers. It is believed that much interesting knowledge can be obtained from Indians, Mexicans and half-breeds, and that, consequently, Indian agencies and reservations are particularly favorable fields for our investigation. Such knowledge will be most acceptible when based upon known facts or experiments.

In order to assist in the study of the habits, properties and uses of medicinal plants, the Sub-commission undertakes to furnish the name of any plant-specimen received, together with any desired information available. Owing to the diversity in the common names of many plants it will be necessary for reports, when not furnished by botanists or others qualified to state the botanic names with certainty, to accompany the same with some specimen of the plant sufficient for its identification. While the Sub-commission will endeavor to determine the plant from any portion of it which may be sent, it should be appreciated that the labor of identification is very greatly decreased, and its usefulness increased, by the possession of complete material, that is, leaf, flower and fruit, and in the case of small plants, the underground portion also. It is best to dry such specimens thoroughly, in a flat condition under pressure, before mailing. While any convenient means for accomplishing this result may be employed, the following procedure is recommended: Select a flowering or fruiting branch, as the case may be, which when pressed shall not exceed sixteen inches in length by ten inches in width. If the plant be a herb two or three feet high, it may be doubled to bring it within these measurements. If it possess root leaves, some of these should be included. Lay the specimen flat in a fold of newspaper and place this in a pile of newspapers, carpet felting, or some other form of paper which readily absorbs moisture, and place the pile in a dry place under a pressure of about twenty to thirty pounds, sufficient to keep the leaves from wrinkling as they dry. If a number of specimens are pressed at the same time, each is to be separated from the others by three or four folded newspapers or an equivalent in other kinds of paper. In twelve to twenty-four hours these papers will be found saturated with the absorbed moisture and the fold containing the specimen should be transferred to dry ones. This change should be repeated for from two to five days according to the state of the weather, the place where the drying is done, the fleshiness of the specimens, etc. The best way to secure the required pressure is by means of a pair of strong straps, though weights will do. The best place for drying is beside a hot kitchen range. When dry the specimens should be mailed between cardboards or some other light but stiff materials which will not bend in transit. It is a most important matter that the name and address of the sender should be attached to the package and that the specimens, if more than one, should be numbered, the sender retaining also specimens bearing the same number, to facilitate any correspondence which may follow. The Sub-commission requests that, so far as practicable, all plants sent be represented by at least four specimens.

[Signed] H. H. Rusby, M.D.,
Chairman of the General Commission, New York Coll. of Phar.
Valery Havard, M.D.,
Chairman of the Sub-commission, Fort Slocum, David's Island, New York.

Washington.

Washington Asylum Hospital.—The Commissioners have appointed Dr. D. Percey Hickling visiting physician to the Washington Asylum Hospital.

Coroner Appointed.—The Commissioners have appointed Dr. William P. Carr the coroner for the District of Columbia, vice Dr. Charles M. Hammett resigned.

A Death from Hydrophobia.—Health Officer Woodward, Deputy Coroner Glazebrook, Drs. Thompson, Barker and Winter have made a postmortem examination of the case of the young man who died during the present week of supposed hydrophobia, from a dog bite, and will have a bacteriologic test made by Professor Norgaard of the United States Agricultural Department. This is the first time the human body has been so examined in the District.

A New Quiz Class.—Dr. F. S. Nash, late U. S. N. has started a quiz class to prepare physicians for entering the medical department of the Army and Navy and Marine-Hospital Service.

Hospital Babies May Cry.—The crying of infants in the Washington Hospital for Foundlings has been the cause of considerable complaint by residents in that vicinity and resulted in a charge of "nuisance" being preferred to the courts and investigated by the grand jury. The grand jury refused to indite the Hospital as a nuisance or gag the babies, and makes the following report: "Complaint having been made in due form of the Washington Hospital for Foundlings as a nuisance, we, the grand jurors, after careful inspection and investigation, hereby submit the following report: We personally visited the Washington Hospital for Foundlings, and found the same to be in excellent sanitary condition and a well-conducted institution. While there is some annoyance from the crying of babies during the warm season, as has been testified to by reputable citizens, we know of no remedy to stop it, and do not think the grievance of those complaining sufficient to justify us in declaring this humane and useful institution a nuisance. We recommend, however, that the authorities be requested and, if possible, required to double their present force of nurses for night duty, as the present force is inadequate to properly care for the children. We further recommend that if it be possible to do so, the children be removed to the country during the heated term. Should a suitable place be obtained for these helpless infants during the warm months it would be of great benefit to the children, besides removing the existing cause of complaint of the residents, as they allege no annoyance at other seasons."

Annual Report of the Health Officer.—The annual report of Health Officer Woodward has been transmitted to the Commissioners of the District and is now printed as a public document. There occurred during the year 5,737 deaths. Of these 3,216 were white and 2,521 were colored. The general death rate was 20.71 per thousand. This is the lowest point reached for the past twenty-two years. A satisfactory feature of the year's mortality table is the very considerable diminution in the deaths from "zymotic diseases." The entire number of such deaths recorded was 891, while during the preceding year it was 1,051. In certain diseases of this class the death list shows an increase. Thus the number of fatal cases of diphtheria rose from 75 to 110; of whooping-cough, from 22 to 65, and of grip from 53 to 118. The decrease in the total number of deaths of this class is accounted for by the diminution in the number of fatal cases of measles from 70 to 3; of scarlet fever from 13 to 1; of croup (so called), from 9 to 6; of typhoid fever, from 228 to 117; of malarial fever (so-called), from 81 to 57, and of diarrheal diseases, from 168 to 358. The number of deaths from diphtheria has not during any previous year fallen so low since 1889. The actual number of cases of this disease which were reported was 618. There is no previous record of any year with but a single death from scarlet fever. He says while it is not entirely safe to base conclusions upon this improvement in the death rate for a single year, yet its coincidence with the closing of a very considerable number of surface wells; with the replacement of more than a thousand box-privies by water-closets, and the proper drainage of the premises: and with a closer supervision of the milk supply is very suggestive of some relation of cause and effect, and possibly justifies us in expecting still further improvement in the future. The present fall in the typhoid fever death rate is especially satisfactory, as it had continually increased since 1887. The death rate from this disease for the past year (.53 per thousand) is the lowest since 1884, and is considerably lower than that for the past twenty-two years (.64). The number of deaths from tuberculosis was 858, while during the preceding year there were 977. The number of deaths from suicide was 57, an increase of 9 over the corresponding figures for the preceding year, and an increase of 6, or almost 15 per cent. over the highest number previously recorded. The average number of suicides per annum during the past twenty-two years has been 17.2. The number of births reported was 4,573, which is probably at least one-third less than the number which actually occurred, owing to the carelessness of the physicians in making the returns.

THE PUBLIC SERVICE.

Army Changes. Official List of Changes in the Stations and duties of officers serving in the Medical Department, U. S. Army, from July 17 to 23, 1897.

First Lieut. Henry R. Stiles, Asst. Surgeon, so much of the order as directs him to report for duty, is amended so as to direct him to report for duty at Ft. Preble, Maine, relieving Capt. Henry S. T. Harris, Asst. Surgeon.

Capt. Robert R. Ball, Asst. Surgeon (Ft. Adams, R. I.), extension of leave of absence granted is extended until Oct. 15, 1897.

Capt. Marlborough C. Wyeth, Asst. Surgeon, upon the arrival of Lieut. Lewis at Ft. McPherson, Ga., will take station at Baltimore, Md., and assume the duties of attending surgeon and examiner of recruits, relieving Capt. W. Fitzhugh Carter, Asst. Surgeon. Capt. Carter will report Oct. 4, 1897, for examination as to his fitness for promotion, and on completion thereof ordered to Ft. Assiniboine, Mont., relieving Capt. George E. Bushnell, Asst. Surgeon. Capt. Bushnell, upon being thus relieved, ordered to take station at Boston, Mass., and assume duties of attending surgeon and examiner of recruits.

Capt. George McCreery, Asst. Surgeon, is relieved from duty as attending surgeon and examiner of recruits at Boston, Mass., and ordered to report at the Soldiers Home near Washington, D. C., for temporary duty, relieving Capt. Charles M. Gandy, Asst. Surgeon.

Capt. Walter D. McCaw, Asst. Surgeon, upon the arrival of Capt. Wells at Ft. Ringgold, Texas, is relieved from duty at that post, and ordered to Ft. Thomas, Ky., for duty.

First Lieut. Benjamin Brooke, Asst. Surgeon, is relieved from duty at Ft. Thomas, Ky., and ordered to Army and Navy General Hospital, Hot Springs, Ark., for temporary duty at that hospital.

Capt. Frank R. Keefer, Asst. Surgeon, is relieved from duty at Washington Bks., D. C., to take effect upon the expiration of his present leave of absence, and ordered to Ft. Sam Houston, Texas, for duty.

First Lieut. Alexander N. Stark, Asst. Surgeon, upon the arrival of Capt. Keefer at Ft. Sam Houston, is relieved from duty at that post, and ordered to Washington Bks., D. C., for duty.

Capt. Charles M. Gandy, Asst. Surgeon, upon the arrival of Lieut. Stark at Washington Bks., is relieved from duty at that post, and ordered to Ft. Mason, Cal., relieving Capt. George M. Wells, Asst. Surgeon. Capt. Wells, on being thus relieved, ordered to Ft. Ringgold, Texas, for duty.

Capt. Henry S. T. Harris, Asst. Surgeon, on being relieved at Ft. Preble, is ordered to Ft. Washakie, Wyo., relieving Capt. Joseph T. Clarke, Asst. Surgeon. Capt. Clarke, on being thus relieved, is ordered to Columbus Bks., Ohio.

So much of paragraph 16, S. O. 162, A. G. O., July 16, 1897, as relates to the officers hereinafter named is amended to read as follows:

Capt. Frank R. Keefer, Asst. Surgeon, is relieved from duty at Washington Bks., D., C., to take effect upon expiration of his present leave, and ordered to Ft. Walla Walla, Washington, for duty.

Capt. William D. Crosby, Asst. Surgeon, upon being relieved from duty at Ft. Missoula, Mont., is ordered to Ft. Sam Houston, Texas, for duty.

First Lieut. Alexander H. Stark, Asst. Surgeon, upon arrival of Capt. Crosby at Ft. Sam Houston, Texas, is ordered to Washington Bks., D.C., for duty.

Capt. Henry S. T. Harris, Asst. Surgeon, upon being relieved from duty at Ft. Preble, Maine, by First Lieut Henry R. Stiles, Asst. Surgeon, is ordered to Ft. Washakie, Wyo., for duty, relieving Capt. Joseph T. Clarke, Asst. Surgeon.

Major William C. Shannon, Surgeon (Jackson Bks., La.), leave of absence granted on surgeon's certificate of disability is extended three months on surgeon's certificate of disability.

Major Paul R. Brown, Surgeon (Ft. Hamilton, N. Y.), ordered to report to Col. Charles C. Byrne, Asst. Surgeon-General, president of the Army retiring board, appointed to meet at Ft. Columbus, N. Y., for examination by the board.

First Lieut. William E. Richards, Asst. Surgeon, is relieved from duty at Ft. Grant, Ariz., and ordered to report Sept. 20, 1897, for duty at Ft. Apache, Ariz.

First Lieut. William F. Lewis, Asst. Surgeon, upon the arrival of Lieut. Richards at Ft. Apache, Ariz., is ordered to Ft. McPherson, Ga., for duty.

Capt. William H. Arthur, Asst. Surgeon, will be relieved from duty at Ft. Myer, Va., on Oct. 1, 1897, and ordered to Philadelphia, Pa., and assume duties of attending surgeon and examiner of recruits, relieving Capt. Rudolph G. Ebert, Asst. Surgeon. Capt. Ebert, upon being thus relieved, ordered to report Oct. 4, 1897, for examination for promotion, and upon completion thereof ordered to take station at Ft. Missoula, Mont., relieving Capt. William D. Crosby, Asst. Surgeon. Capt. Crosby, on being thus relieved, is ordered to Ft. Preble, Maine, relieving Capt. Henry S. T. Harris, Asst. Surgeon.

Capt. Charles M. Gandy, Asst. Surgeon, is granted leave of absence for two months and ten days, to take effect upon being relieved from temporary duty at the Soldiers' Home near Washington, D. C., and will, upon the expiration of leave of absence, report for duty at Ft. Mason, Cal.

ORIGINAL ARTICLES.

RHEUMATOID ARTHRITIS, WITH REPORT OF TWO CASES.

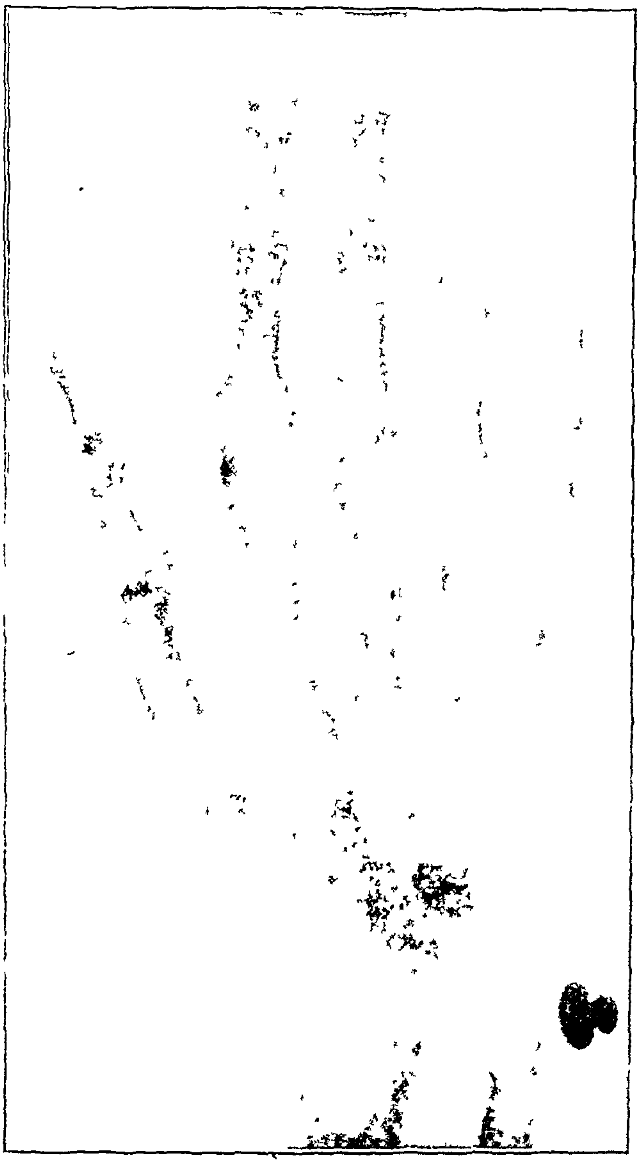
Presented to the Section on Practice of Medicine, at the Forty eighth Annual Meeting of the American Medical Association, at Philadelphia, Pa, June 1 4, 1897

BY DAVID RIESMAN, M.D.
ADJUNCT PROFESSOR OF CLINICAL MEDICINE, PHILADELPHIA POLYCLINIC, DEMONSTRATOR OF PATHOLOGIC HISTOLOGY, UNIVERSITY OF PENNSYLVANIA.
PHILADELPHIA, PA

Despite the increasing literature on the subject of rheumatoid arthritis, the ultimate nature of the disease is far from clearly established, and even at this date we do not positively know just what affections of the joints should be grouped under the name. Nothing so clarifies the nosographic atmosphere as the discovery of causes—only through causal knowledge are we able to separate diseases that are similar and to assign to them a definite place in our systems. How easy it has become for us to define typhoid fever, diphtheria, and malaria, since their etiology has been determined. As we are still unable to point out the true cause of rheumatoid arthritis, it would, I believe, be better, following the example of Virchow, Garrod, and others, to use the phrase *arthritis deformans*, as that expresses the most prominent symptom and is non-committal on the score of pathogenesis.

Morbid anatomy.—The lesions produced by arthritis deformans vary considerably with the period or stage reached by the disease. The earliest changes probably always take place in the articular cartilage, and consist in a perpendicular fibrillation of the hyaline matrix of the surface layers. Almost synchronous with this is is a proliferation of the cartilage cells. Softening and fatty processes develop later and cause erosion and disappearance of the cartilage, especially at the lateral parts of the joints, where pressure is greatest. Islands of cartilage may remain and undergo thickening. In the deeper parts of the cartilage ossification may take place. Very marked alterations also affect the synovial membrane and capsular ligament, which become irregularly thickened and distended from the formation of numerous villous processes. Chondrification and even ossification may take place in the latter, and by detachment free bodies may be formed. The bone changes are very striking. In those places where the cartilage is eroded, friction leads to polishing of the exposed bone. In the subchondral areas bone absorption takes place—here it can not be due to friction—and the amount of destruction may reach astounding proportions. While all these changes are in progress new bone is being formed in other parts of the joint, and thereby extensive irregular osteophytic outgrowths are produced, which may entirely surround the joint and contribute to the enlargement. Partial or complete ankylosis, not rarely in strange positions, is a common terminal result.

At times the disease is strictly limited to parts of the articular surfaces, as in the cases reported by Bennett.[1] In one of these the scapulo-humeral joint was normal, but the lesser tuberosity of the humerus was ground down to its base and the inner lip of the bicipital groove was gone. In a radius, from another case, the depression for the scaphoid bone was cut clean away, while the fossa for the semilunar bone was free from disease.

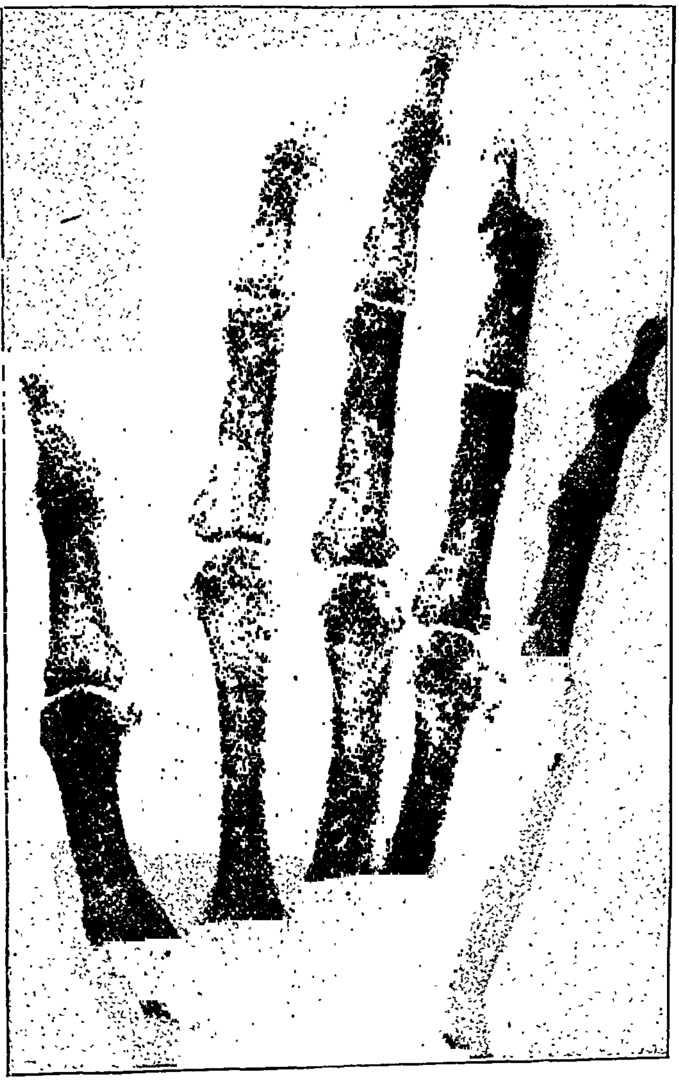


Next to the arthritis the most important morbid change is an atrophy of the muscles in the neighborhood of the affected joint. The muscles are paler than normal, and microscopically are seen to be smaller, but their striation is preserved.

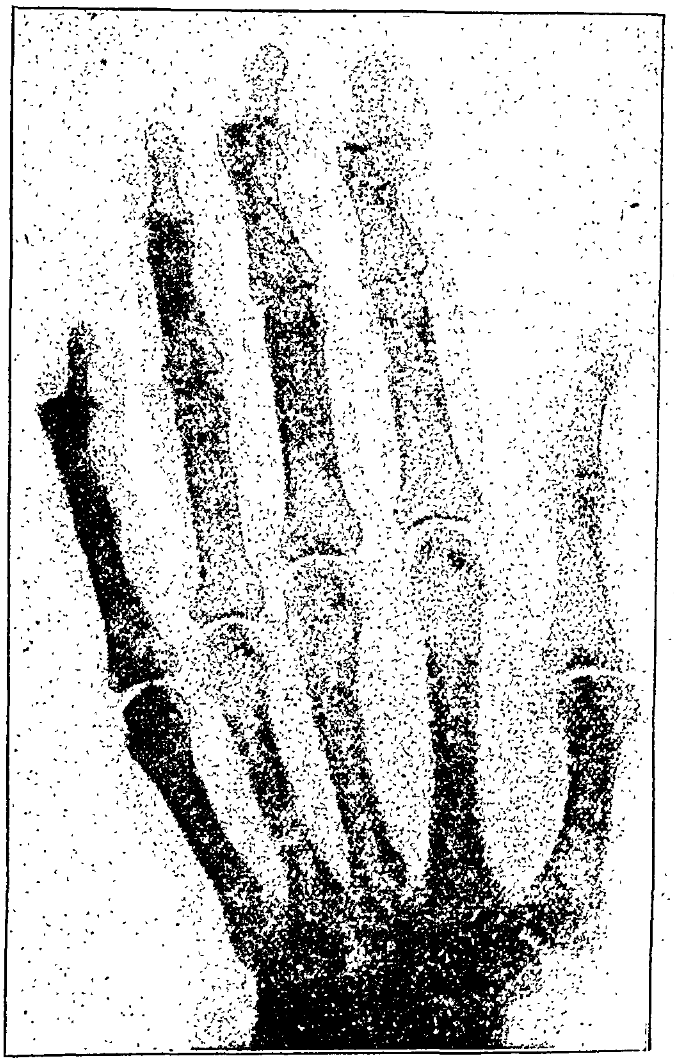
---

[1] Bennett. Dublin Jour Med [illegible]

The symptoms and manifestations of arthritis deformans permit us to distinguish several clinical varieties which, following in the main the systematic writers, I would designate as follows: 1. *Arthritis deformans* of severe type. 2. *Arthritis deformans* of mild type. 3. *Localized form,* and perhaps, 4. *Arthropathy,* or that form associated with gross lesions of the nervous system. Although it is customary to separate sharply the severe form from the mild, we must admit that there are many gradations bridging the chasm between the mildest, Heberden's nodes, and the severest, the terribly deforming variety.



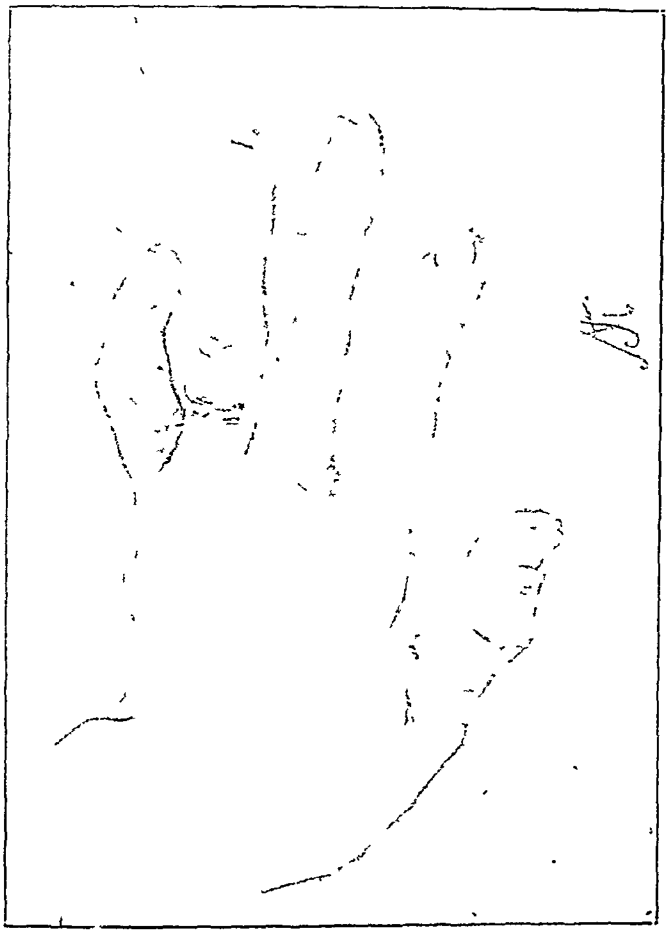
Time is too brief to enter into the symptomatology of the various forms, but I would call your attention to the revelations of the Roentgen ray when employed in the study of this disease, by passing around these radiographs kindly made for me by Dr. Stern. It may not be out of place to say a few words about the nodes to which Heberden called attention in the following words: "What are those little hard knobs (*digitorum nodi*) about the size of a small pea, which are frequently seen upon the fingers, particularly a little below the top near the joint? They have no connection with the gout, being found in persons who never had it; they continue for life, and being hardly ever attended with pain or disposed to become sores, are rather unsightly than inconvenient, though they must be some hindrance to the free use of the fingers." (Commentaries, 1818, p. 109.) The affection gives rise to an enlargement of the terminal joints of the fingers, which may be spindle-shaped or abruptly nodular; in time, deflection of the last phalanx occurs, and, differing from the hand as a whole, which is tilted toward the ulnar side, it takes place toward the radial side. There is also a slight rotation. It is commonly stated that the thumb is not affected, but while, as a rule, it escapes, it does not always do so, and I have recently seen two cases in which it was involved. Heberden's nodes are found most commonly in women, and begin to develop at the menopause or later. They occur also at an earlier period before the catamenia have ceased



I show a pencil sketch of a hand (p. 259) the seat of early rheumatoid changes, from a woman of 40, in whom the disease developed two years ago, a month after an attack of diphtheria. I may add that the patient has had three attacks of articular rheumatism, the last fifteen years ago, and has suffered for a number of years from exophthalmic goiter. Menstruation is regular.

Although the disease, when it manifests itself as Heberden's nodes, shows usually no tendency to spread, I have seen it do so in some cases that were under 50 years of age when the malady commenced. (In one patient it was associated with deformity and stiffening of the wrists.) For this reason I have ventured to assert that we can not separate Heberden's nodes sharply from the other forms, and am of the opinion that they are a manifestation of the same disease and are not a variety of gout. As we see the condition in aged women and men, it is generally not progressive.

Heberden's nodes are very common in women who have done much washing, but I have seen them in those who have never toiled at the wash-tub.



When we come to consider the pathogenesis of the disease, we are confronted by a multiplicity of theories that is quite perplexing. They may be classified in the following way:

1. *That the disease is a form of chronic rheumatism*, a theory maintained by Tooth, Charcot, Mitchell Bruce and others. Against this may be urged: *a*, the rarity of endocarditis and other visceral lesions in arthritis deformans; *b*, the exciting causes of true rheumatism can generally not be traced in the typical severe form of the other disease; *c*, the frequency of the affection in women, the reverse being true in the case of rheumatism; *d*, the usual failure of the salicylates.

2. *That the disease is a product of the mixture, in varying proportions, of the inherited taints of rheumatism and gout*, causing in one case the gouty element, in another the rheumatic element to preponderate.

3. *That it is allied to gout and is due to uric acid*, which causes the joint changes, but is again dissolved out, while in gout it remains in the joints (Haig). The view that arthritis deformans is a modified form of gout has long been abandoned. The factors leading to the development of the two diseases are totally different; the preponderance of the female sex, the absence of tophi, the occurrence of arthritis deformans in early childhood, all serve to distinguish it from gout.

4. *That it is of nervous origin.* In favor of this are the symmetric distribution of the lesions, the muscular atrophies, the absence of visceral lesions, and the general *bien-être* of the patients, which in a sense corresponds with that seen in many cases of chronic spinal sclerosis. The nervous theory appears under several phases: *a*, It has been held, as suggested many years ago by J. K. Mitchell, that arthritis deformans is primarily *a spinal disease*. The great resemblance between the joint changes of rheumatoid arthritis and the arthropathies of tabes dorsalis and syringomyelia might seem to lend support to this view; however, in true rheumatoid arthritis the spinal cord, when examined, has always been found normal. Yet there may be nutritive changes in the cord that elude our search. *b*, The disease has been ascribed to a *peripheral neuritis*, largely on the strength of the changes found (Pitres and Vaillard) in the nerves contiguous to the joints, but these neuritic phenomena are more likely consequential or at the most synchronous rather than antecedent, and accompany arthritic muscular atrophies of other kinds. *c*, The disease is a *trophic affection*—a trophoneurosis. Under the vague head of trophoneuroses we are accustomed to class a number of affections, such as scleroderma, Raynaud's disease, acromegaly, characterized by marked structural changes, for which we have no satisfactory explanation. The nervous system undoubtedly governs the nutrition of all parts of the body, whether by reason of its power to regulate the blood supply or through the exercise of a direct trophic influence, must for the present be left unanswered. It is conceivable that, as the joints are under the control of the same forces, a disturbance of the latter might bring about nutritional changes in the articular structures. But the factor that underlies the nervous disturbance remains hidden. *d*, *Uterine or utero-ovarian irritation* acting reflexly through the nervous system (Ord, Armstrong).

5. *That it is infectious.* This view was first promulgated by Schueller (Langenbeck's *Archiv f. klin. Chir.*, 1892, Bd. 45, Heft 1; *Berlin. klin. Woch.*, 1893, Sept. 4), who found a bacillus in the joints with cultures of which he was able to produce articular changes in animals quite analogous to those observed in man. More recently Bannatyne, Wohlmann and Blaxall (*Lancet*, April 25, 1896) have found a peculiar bacillus, both in the joints and at times in the blood, with which, however, they were not successful in producing unequivocal joint changes in animals.

I have given these theories at some length, with comments upon some, but in the end it can only be said that our present knowledge does not warrant a final decision on the question of the pathogenesis of arthritis deformans.

It is unnecessary to enter into a detailed account of the symptoms of the severe form, that associated with marked deformity and great restriction in mobility of the joints. I give here a summary of two cases, as they illustrate the symptoms quite well:

Case 1.—Mrs. F., whom I saw with Dr. Clarke of Philadelphia, was born in Pennsylvania, of Irish parents. She has been married sixteen years and has had eight children, the youngest of whom is 5 years old. The family history is exceptionally good. Mrs. F. was never very strong; menstruation began at 12 years of age, and was always regular except when under rupted by pregnancy and lactation. From her 17th to 38th year, the latter being her age at the time the present disease began, she was subject every spring and fall to peculiar weak spells characterized by palpitation and a feeling of debility. Ten years ago she had an attack of acute cystitis. The *arthritis deformans* began five years ago, during her last pregnancy, with pains, soreness, and stiffness in the cervical vertebræ, and on the evening before her confinement the left shoulder and arm became similarly affected. During the puerperium the other joints were involved in the following order: Right shoulder, right knee and ankle, left knee and ankle, and by the end of the sixth week both elbows, wrists, and hands. She also had slight stiffness, soreness, and tenderness in the temporo-maxillary joints. Pain has disappeared in the joints most severely diseased. Her present condition is as follows: The left elbow is somewhat enlarged, especially on the inner side, and slightly flexed; pronation and supination are restricted, and there is distinct grating on movement. The left wrist is quite stiff, backward motion being particularly limited; grating is also present. The natural contour of the wrist has disappeared, and the forearm, wrist, and hand present a continuous, unbroken outline. The back of the hand is sunken in, and the knuckles are unduly prominent. There is atrophy of the interossei and of the thenar and hypothenar eminences. Preternatural mobility of all the knuckle joints, including the metacarpophalangeal joint of the thumb, is present. The middle joints of the fingers are slightly enlarged and tender to the touch; the last joints are apparently free from disease, but with that of the thumb are hyperextended. The right elbow is enlarged and partly flexed; rotation and supination are more limited than on the left side, and the wrist is completely ankylosed and immovable. The right hand is almost like the left, except that the hyperextension of the last joints is confined to the middle and ring fingers, and is but slight. There is marked roughening and grating of the knuckle joint of the right index and enlargement of the head of the metacarpal bone. The finger is so loose that it can be rotated in a considerable arc on its longitudinal axis. Pain is absent in the joints. The nails of both hands tend to be longitudinally ridged. The cervical spine is affected, the rotary movements of the head being embarrassed. There is impaired mobility of both shoulder joints.

Lower extremities.—The right knee is enlarged and its motion impaired, especially extension. The patella does not float; the synovial capsule is thickened. Motion gives rise to pain and to cracking audible at a distance. The movements of the right ankle are impaired; the toes are stiff, but not markedly deformed. There is slight edema of the leg. The left knee is less affected than the right; the edema of the foot and leg is marked.

Upon moving the larynx a loud, rasping and grating sound is produced by the friction of the roughened cartilages on each other; the voice is somewhat hoarse. The joints of the lower jaw are slightly stiff and the mouth can not be opened to its full width. The thyroid gland is not enlarged. Hands and feet are cold and moist; sweating of other parts, the patient says, is rare. There is no pigmentation except on the instep, ankle joint, and lower part of the leg; its appearance was preceded by a severe burning sensation in the pigmented areas. The heart sounds are normal, the pulse 112. The patient enjoys fair general health and has a good appetite. She has used crutches for a year, but walks with great difficulty and is absolutely unable to climb stairs. She is gradually getting shorter in height on account of increasing flexion of the knees. Blood examination: hemoglobin 80 per cent.

Of special interest in this case are the involvement of the laryngeal cartilages, the absence of pain in the articulations most extensively diseased, and the great resemblance which the joints bear in their appearance to the arthropathies of spinal diseases. It is worthy of note, too, that the arthritis began during pregnancy.

Rheumatoid arthritis, like diabetes mellitus, appears to be more baneful the younger the patient attacked. In adolescence and early adult life recoveries are rare. The following case illustrates the possibility of arrest and partial cure of the disease:

Case 2.—Miss Martha M., a milliner, 23 years of age, was always healthy, fond of society, and a passionate dancer. Constipation and occasional headaches were her only ailments. The family history is of interest, as the mother is a sufferer from a rather severe form of rheumatoid arthritis—the disease came on at middle life and began with the formation of Heberden's nodes. The father is afflicted with chronic bronchitis and emphysema, and is subject to digestive disturbances, probably lithemic in nature. In the summer of 1893 Miss M. visited the World's Fair, and very injudiciously wandered about the grounds every day until almost exhausted. On her return she went to Atlantic City, and one day, September 4, while bathing had a chill, but recovered quickly and walked with friends until very tired. On the following morning she had a peculiar pricking feeling in the bottom of both heels, which abated somewhat the next day, but did not entirely disappear. Very soon it spread to the balls of the toes on the right foot and later also to those of the left. On Sept. 25, 1893, having stood at the ironing-board for two hours, the pain in the feet became excruciating, and she felt as if she were "walking on hair-brushes." She also experienced acute darting pains in the region of the heart, which somewhat hampered breathing. She was compelled to remain in bed for some time, but had no fever. The metacarpophalangeal joint of the right thumb and the right wrist now became diseased, and were swollen and stiff on motion. She had to be carried down stairs, but was for some time able to walk up stairs unaided. When lying down or sitting with the feet elevated she had no pains. From October 14 she was in bed three weeks, but without any benefit, and at the beginning of 1894 the great-toe joints, the ankles, and the knees became swollen and stiff. She was unable to stand on her feet; it seemed to her as if they were terribly bruised and unable to bear the weight of her body. Her appetite was good and apart from the joint trouble she had no complaint except transitory precordial pains.

I saw the patient at her home March 6, 1894. She was a tall, pale, blonde young woman, fairly well nourished and refined. The left ankle was swollen, but there was no pitting, tenderness or redness of the skin. Both feet seemed to be unnaturally thick, yet were well arched; severe pain was caused by compressing the toes at the heads of the metatarsal bones. The metacarpal joint of the right thumb was greatly enlarged, through an increase in size of the head of the metacarpal bone. Abduction of the thumb was restricted. There was neither tenderness nor spontaneous pain; considerable atrophy of the first dorsal interosseous muscle existed. The grasp of the right hand was almost *nil.* The right wrist was enlarged but not painful or tender; pronation and supination as well as flexion of the right forearm were greatly limited. A soft blowing systolic murmur was audible at the apex of the heart. The bowels were so constipated as to yield only to enemata.

The treatment first employed consisted in alternate hot and cold douches; they were of no benefit. Counter-irritation was also fruitless. On March 14 she had a febrile attack, during which the heart murmur grew louder, gallop-rhythm was superadded, and a soft systolic murmur became audible at the aortic cartilage. Dr. S. Solis-Cohen saw her with me at this time. Under the use of ammonium salicylate the acute symptoms rapidly vanished, but despite various forms of local and internal medication the joint disease progressed, spreading from the ankles, which were both involved, to the knees. The latter became irregularly enlarged and painful, and assumed a state of flexion, but were neither red nor tender to the touch. By May the flexion was very pronounced, the patient being unable to stretch the legs. I then applied an extension apparatus, such as is used for fractured thigh, to both legs, and was able to secure complete extension in about six weeks.

The patient's temperature was as a rule normal or but slightly elevated; the pulse was rapid, 96 to 100; the extremities, particularly the hands and feet, cold and clammy. At long intervals slight febrile movements occurred, rarely lasting more than twenty-four to forty-eight hours. The tongue was nearly always coated, but the appetite and the digestion were usually good. The knee jerks were exaggerated, and there was ankle-clonus; the plantar reflex was present. Sensibility to touch, heat, and cold was not disturbed. The atrophy of the first dorsal interosseus of the right hand grew perceptibly greater; gradually, too, the power of movement in the hand and arm became so restricted that the patient could not comb her hair, and had to feed herself entirely with the left hand. The urine was variable, but usually had a high specific gravity, 1028–1036; once it was only 1011; on one occasion it reduced bismuth subnitrate and turned Fehling's solution green without precipitation; it was free from albumin, and often alkaline in reaction.

Toward the end of June a marked but transitory improvement occurred. In July the dorsal portion of the spine became stiff and painful and the trunk movements restricted. A blister was applied and proved very efficacious; the disease did not spread and perfect suppleness gradually returned. In August the patient's condition was very bad; all the affected joints, feet, ankles, knees, right wrist and hand, were stiff; the skin over the small joints was cyanotic; and she complained of shooting pains in the joints and stiffness of the neck. The right index and right thumb were preternaturally movable, and distinct grating could be heard and felt. In September the darting pains attacked the left thumb and an enlargement of the metacarpophalangeal joint followed. About this time Dr. Pepper saw her with me and agreed as to the nature of the case. At his suggestion, hypodermic injections of the double chlorid of gold and sodium were given twice daily. Later on I placed the patient on thyroid extract, but almost immediately alarming toxic symptoms, those of thyroidism, developed, and the remedy had to be abandoned. Throughout these months she was taking tonics, cod liver oil, arsenic, syrup of the iodid of iron, etc., and also received inunctions of cod liver oil; occasionally salicylates were given; faradic electricity was also tried. By November the legs had again become flexed and extension was reapplied and kept on for two and a half months. Bone-marrow was administered for a few weeks in 1895, but without practical result. The disease continued to advance—the right shoulder became involved, and atrophy of the shoulder and scapular muscles occurred. The circumference of the right arm at the axilla was 3 cm. less than that of the left. At no time was the patient's condition influenced in the slightest degree by change in the weather.

The use of strontium bromid was now begun and, whether *propter hoc* or *post hoc*, the patient began to improve; in April, 1895, she was able to walk around the bed by holding on to the railing; on July 1 she walked out into the yard, but the following day had a relapse and was again confined to bed, internal treatment being continued and systematic massage being given. Improvement now became continuous and progressive, and in November she ventured out and walked eight city squares the first day. Last year and this spring she again worked at her trade, and recently consulted me as to the advisability of getting a bicycle. She tells me she has almost forgotten her long illness, the vestiges of which are, however, unmistakable, though they do not trouble her any. The heart murmur has entirely disappeared; there is now only slight accentuation of the second aortic sound; the pulse is regular but a little rapid. Motion in the shoulder, knee, and ankle joints is perfect; the deformity of the right wrist has nearly disappeared, and that of the right thumb is greatly lessened. Abduction of the thumb is, however, still restricted, and there is occasional crackling in the knee joints when she rises from the sitting posture. The ankle clonus can no longer be elicited.

To recapitulate: A young, healthy woman, with a family history of rheumatoid arthritis and lithemia, was taken ill after a sea bath with peculiar pains, soon followed by joint enlargement, destruction of cartilage, atrophy of the muscles, and contraction of the joints, all fairly symmetric. A heart murmur was present; the knee jerks were exaggerated, and there was ankle clonus. After continuous confinement to bed for seventeen months, improvement set in and was followed by a practical recovery.

The treatment was so varied and manifold that definite conclusions can not be drawn from it, but I beg to call attention to the following points: 1. The importance of preventing contractures and the efficient value for this purpose of the extension apparatus. I am convinced that had it not been applied the patient, although the disease is arrested, would now be unable to stand or walk. It has also occurred to me that an analogous device for the arms in certain cases might be of great service. 2. From the apparent effects of strontium bromid in this and other cases I am led to the view, still tentative however, that it has: *a*, an influence over the pains; *b*, perhaps a power to limit the progress of the disease.

A Characteristic Symptom of Lesions in the Posterior Cranial Fossa is the peculiar dyspnea whenever seated upright, relieved by resuming the reclining position. The breathing becomes very slow, deep, snoring, and interrupted by frequent pauses half a minute long. Two new observations are described in the *Deutsche Med. Woch.*, of June 10. One was caused by a tumor in the fossa, left of the basis cerebri, the other by thrombosis arteriæ basilaris, both fatal.

THE CARDIO-VASCULAR AND RENAL RELATIONS AND MANIFESTATIONS OF GOUT.

Presented to the Section on Practice of Medicine, at the Forty-eighth Annual Meeting of the American Medical Association held at Philadelphia, Pa., June 1-4, 1897.

BY N. S. DAVIS, JR., M.D.

CHICAGO.

That gout and its varied complications are due to toxemia, possibly to uric acid or to other substances which vary in the blood as it does, is generally admitted. Interstitial nephritis, the common renal complication of gout, is so well understood that I need not dwell upon it in this discussion. There are a few points, however, in the course of development of the lesion to which I wish to call attention, for in most text-books and monographs sufficient emphasis is not placed upon them.

It is, of all renal diseases, the most insidious in onset, and it is intermittent in progress. The kidneys are attacked now and again by uric acid or the toxic agent of gout in microscopic areas, which produce active lesions of almost microscopic size. It is true when we examine a kidney which illustrates interstitial nephritis that we find almost the whole parenchyma involved to a greater or less extent, but this extensive lesion has been slowly developed and is due to the confluence of minute changes which have been wrought intermittently. I have spoken of active lesions of microscopic size. These result in a destruction of glomeruli, tubules and arterioles, and when this destruction has been wrought the scar tissue which is left is inert and represents only a loss of renal function.

If the renal changes of gout are looked at in this way they will explain in part the symptomatology of the affection. As the glomeruli are attacked one after the other, not all of them or most of them simultaneously, and as those attacked today may atrophy and become useless before others are involved, the filtration of water from the blood will be modified only by the very few Malpighian bodies actively affected at the time. Therefore only traces of albumin appear in the urine, in marked contrast to the large quantities which appear when the kidneys are involved in parenchymatous inflammation. The atrophic and destructive changes which involve the renal epithelium cause a degree of renal insufficiency to slowly develop. The endarteritis which often obliterates the caliber of the arterioles and the destruction of capillaries in the diseased areas increases blood pressure. This causes the elimination of abnormally large amounts of urine by those glomeruli and renal tubules which are as yet unaffected and healthy.

The insidious and intermittent development of these lesions explains fully the pathognomonic symptoms; polyuria, with traces of albumin, few renal casts, diminished elimination of urinary solids and high arterial tension.

High arterial tension in gout is due in part to uric acid or other toxic substances in the blood which increase the tonus of the arterioles. The destructive agent, whatever it is, that attacks the kidneys produces also arterio-sclerosis or atheroma in the arteries of other tissues. The thickened and rigid walls of the arteries impede circulation, which stimulates the heart to contract more forcefully. This is a second factor producing increased blood pressure. Arterio-sclerosis in the kidneys, in the central nervous system, in the various tissues of the body, often produces serious or fatal complications in those who have a gouty diathesis. Because the walls of arteries are weakened by disease and stretched by blood under unusual pressure aneurysms sometimes develop in the smaller or larger arteries. The smaller ones are frequently the cause of apoplexy.

The commonest and most characteristic cardiac change associated with gout is hypertrophy. The left ventricle is chiefly thickened, although when the heart is hypertrophied both ventricles are affected more or less. The cardiac hypertrophy is, without doubt, due to increased work which the heart has to do because of the destruction of some arteries and capillaries and diminished caliber and rigidity of others. These changes in the arteries generally necessitate compensatory cardiac hypertrophy and as the arterial changes become more widely diffused, little by little and intermittently, the cardiac hypertrophy slowly increases so long as the nutrition of the individual is good. Ultimately cardiac compensation becomes impossible, cardiac fatigue, dilatation and exhaustion develop. Endocarditis and pericarditis almost never complicate gout. In this respect the contrast with articular rheumatism is striking. It is true that deposits of urates have been found on the valves in gout, but such cases are extremely rare and exceptional.

These various changes in the kidneys, arteries and heart may occur in podagra or characteristic gout, but are more frequently seen independent of it and often themselves constitute the most marked manifestations of a gouty diathesis.

Treatment, to be of value, must be hygienic. It will aim to prevent the accumulation in the blood of those substances, uric acid or whatever they may be, which produce the vascular, cardiac and renal changes. Necessarily treatment must be continued for a long time. By removing the cause of these complications of gout their progress may be brought to a halt and a patient may be made comparatively comfortable. It is impossible to restore renal tubules and glomeruli which have been destroyed. But it is rare that the renal changes are so extensive that they, of themselves, will prove destructive of life. In almost every instance, when the disease is recognized, enough healthy renal tissue exists so that if its cause is removed the kidneys will continue to do their work fairly well, and maintain a condition of physiologic health even though they are anatomically much deformed. The same can be said of the inhibition of the growing cardiac and vascular lesions by suitable treatment.

CHRONIC INFLAMMATION AND ULCERATION OF THE DUODENUM, WITH RESULTANT REFLEXES.

Presented to the Section on Practice of Medicine, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY JOHN M. ALLEN, A.M., M.D.
PROFESSOR OF THE PRINCIPLES AND PRACTICE OF MEDICINE AND PRESIDENT UNIVERSITY MEDICAL COLLEGE, KANSAS CITY, MO.
LIBERTY, MO.

The duodenum is abundantly supplied with arterial blood. Its veins empty into the portal vein, any obstruction of which, either from the lungs, liver or heart, produces passive congestion of this organ. Its nervous connection with the brain is by branches from the par vagum and with the spinal cord by branches from it, with the sympathetic system by branches from the solar plexus, and with the thoracic plexus by the splanchnic nerve. It has within its structure the plexus of Meisner and Auerbach. It is studded with the glands of Lieberkühn and Brunner, and with solitary glands as well as lymphatics. It is the physiologic receptacle of the chyme which is often perverted by functional disease of the stomach or overrepletion, either of which may be highly irritating to the duodenum. It also receives the secretion from the liver and pancreas and performs, possibly, as important a function in the digestive process as does the stomach, and is as frequently subject to physiologic hyperemia. Indeed, there is no structure in the human body which is so often exposed, both internally and externally, to as many varieties of disease-producing forces as the duodenum. It is directly connected with the brain, spinal cord and sympathetic system as no other portion of the alimentary canal is, which fact makes it the great reflex center of this canal.

Careful analysis of a large number of cases of reflex irritation supposed to have originated at other points of this canal, disclosed the fact they always originated in the duodenum. It is far more frequently diseased than one would infer from the scant literature on the subject.

In my clinic at the University Medical College of Kansas City, Mo , 10 per cent. of the cases had chronic inflammation and ulceration of the duodenum. In my private practice the percentage is about the same. As compared with chronic gastritis—or so-called catarrh of the stomach—it is far more frequent. In 17,000 clinical patients I found 666 of duodenal disease, and only one case of chronic gastritis and one of ulcer of the stomach. In fact, I never saw a case of chronic inflammation of the stomach, excluding chemic and other irritants as causative, that did not proceed by extension from inflammation of the duodenum. It is most often found between the ages of 20 and 40, but it frequently occurs in childhood, the result of enterocolitis or cholera infantum. It occurs in females more often than in males because of their more numerous reflexes.

Typhoid fever is the most frequent cause. Other causes are phthisis pulmonalis, functional disease of the stomach, croupous dysentery by extension, the exanthematous fevers, particularly rubeola, acute inflammation of the organ, passive congestion, burns, acute inflammation associated with pneumonia, which obstructs the bile ducts, producing what the older writers called bilious pneumonia, and reflex irritation, the result of disease of the uterus and appendages.

Brown-Séquard asserted years ago that reflex irritation was sufficient to arrest secretion and nutrition, and produce inflammation. This fact is beautifully illustrated in severe burns of the skin, which, by reflex irritation, result in acute inflammation of the duodenum, and *vice versa*, irritation of the duodenum will produce inflammation of the skin, as in urticaria and eczema. In childhood we have a clear example of the effect of irritation of the intestinal canal, producing reflex irritation of the nerve centers, attended with functionary changes in the blood of these centers, thereby producing convulsions.

Esquirol, Pinel, Cullen and others believed and taught that gastro-intestinal irritation was a frequent cause of insanity, yet they were not able to give a reason why this should be so. In the light of modern science and our knowledge of reflex irritation producing fluctionary changes in the blood, they were not far wrong, as is illustrated by the following case:

Case 1.—June 10, 1875, Mr. P., aged 35, no hereditary tendency to insanity, a well-to do farmer, had always enjoyed excellent health until three years before, when he had an attack of typhoid fever with serious bowel complications; during convalescence there was no restriction in his diet, which had much to do in leaving him with a chronic inflammation and ulceration of the duodenum. In 1877 he presented himself to me for treatment. I found him suffering with melancholia, with suicidal tendency, dependent upon reflex irritation caused by chronic inflammation of the duodenum. I placed him under treatment for this disease. As soon as the irritation was controlled he began to improve, and so continued steadily until restored to health.

In the last twenty years I have treated seven other cases of insanity, the causes of which could be clearly traced to reflex irritation produced by disease of the duodenum. Four of these cases were the after-effects of typhoid fever; two of them were from functional diseases of the stomach, and the remaining one was from acute duodenitis, associated with pneumonia, which became chronic.

Epilepsy as caused by reflex irritation.—Statistics show, excluding traumatism, heredity and alcoholism as causative forces in producing epilepsy, more than one half of the cases of this disease begin in childhood. It is my opinion that a very large percentage is the result of reflex irritation caused by chronic inflammation of the duodenum, as is illustrated by the following case:

Case 2.—May, 1870, I was called to see a child 2 years old. *History.*—The previous summer, while teething, he suffered for six or seven weeks with entero colitis; for five or six weeks before I saw him he had been suffering from unconscious spells of *petit mal*; the day before he had *petit gravior.* Diagnosing epilepsy dependent upon reflex irritation caused by chronic inflammation of the duodenum, I placed him under treatment for this disease and he eventually recovered.

Case 3.—In November, 1880, I was consulted in regard to a child 8 years old, who had begun to have *petit mal* in July, 1880. The disease was now *petit gravior.* There was not sufficient history of intestinal disease to point in that direction for cause, excepting malnutrition, nor was there any hereditary history of epilepsy or neuropathic diathesis. January, 1881, the child died of broncho-pneumonia. Postmortem examination revealed two ulcers in the upper portion of the duodenum surrounded by zones of inflammation.

I have treated seventeen other cases of epilepsy, between the ages of 2 and 17 years, caused by reflex irritation excited by duodenal disease. Those I have seen during the first six months of the existence of the disease have recovered; one at the end of the second year recovered; of those in whom the disease had existed over three years only one recovered, the others were not benefited. I think it is fair and logical to believe that if the cases are seen early a large percentage of them can be cured; but when the epilepsy has existed for more than two or three years, although you may relieve the cause of the irritation, the fluctionary changes in the blood become a fixed habit, and is more difficult to treat than the primary cause of duodenal irritation; add to this the strong possibility of changes in the structure of the nerve centers, caused by perverted nutrition, the result of the functionary changes in the blood plus habit, and the case then becomes hopeless. In a large majority of the cases of duodenal disease the patient suffers more or less from neurasthenia, but there are cases in which it is the prominent effect of reflex irritation.

Case 1.—Age 34, female, married, mother of four children. Family history perfect; said to have had lacerated cervix uteri, for which she was operated on with the assurance that a cure of this would relieve her neurasthenia. This was in 1881; she was not benefited by the operation; had had typhoid fever in 1880. I saw her in 1883, when she had suffered from neurasthenia since the middle of 1881. I diagnosed chronic inflammation and ulceration of the duodenum with resultant reflexes. I placed her under a course of treatment and at the end of four months she had entirely recovered.

Pharynx and nasal cavities.—It frequently happens that we find pharyngitis and rhinitis associated with chronic duoduenal diseases. I report the following case: Four years ago Prof. J. E. Logan of the University Medical College of Kansas City, Mo., referred a case to me for treatment, with the statement that the rhinitis, which was attended with distressing sneezing, was caused by reflex irritation. On examination of the patient I found her suffering from chronic inflammation and ulceration of the duodenum, caused by long continued functional indigestion of the stomach. I placed her under treatmant for duodenal disease only, giving no attention whatever to the nasal or pharyngeal inflammation. She rapidly improved, ceased sneezing within a week. and at the end of four months was perfectly well.

Diseases of the skin.—That urticaria is entirely dependent upon reflex irritation originating in the duodenum can not be doubted. The same is true of many of the forms of eczema, a fact which I have verified in a large number of cases by diagnosing the existence of duodenal disease, the successful treatment of which entirely relieved the skin disease.

Pruritus of the skin.—A case of this disease had been under the treatment of several distinguished dermatologists without relief. I diagnosed chronic duodenal disease following an attack of rubeola producing reflex irritation. The patient was placed under treatment, and as soon as the duodenal disease began to improve, thereby lessening the reflex irritation, the pruritus began to subside, and she was entirely relieved.

In duodenal disease the functional action of the heart is interfered with. It is either increased in frequency and decreased in force or merely decreased in frequency. I have seen it, in different cases, vary in number of strokes from 35 to 120 beats per minute. In many cases the reflex phenomena appear in the lungs, in which there is sighing respiration or asthma. Anemia of the brain is not uncommon. Local hyperemias of the brain with insomnia is also very common.

Over twenty-five years ago my attention was called to the character of food recommended for diabetic persons, which then had no better reason for its use than "that it was best," also to the exclusion of saccharin matter with no better explanation than the above. About that time I treated two cases of pachymeningitis, which were followed by diabetes mellitus caused clearly from irritation or pathologic changes near the fourth ventricle of the brain. I soon learned that opium had no controlling influence in the cases whatever over the amount of urine secreted, differing in this from any case in which I had used it before. Finding later that chronic inflammation and ulceration of the duodenum always preceded all the cases of diabetes mellitus which I treated, I concluded that the real benefit of opium was its controlling influence over peripheral irritation, thereby lessening the reflex influence. My attention was then called to the close relations between this disease and diabetes mellitus. Since that time I have carefully examined more than thirty cases of diabetes mellitus, and found that this disease of the duodenum had preceded every one of them. Seven of these cases I have verified by postmortem examinations. In each I found chronic inflammation and ulcerations of the duodenum. There was no other pathologic change of structure except in one where the liver was affected.

It may be a question whether the relation of these two diseases is the result of peripheral irritation producing reflex irritation, thereby affecting the nutrition of the nerve centers that preside over the conversion of starchy and other matters into saccharin matter, or whether it is the interruption of the function of the duodenum and its accessories which arrests or prevents normal metabolic and anabolic changes in our food, and by natural selection the defective products of saccharin matter (glucocids) are taken up by the absorbents and depurated by the kidneys.

The principles that should govern the treatment of this disease and its reflexes are as follows: 1. The organ should be given rest from physiologic hyperemias by excluding oleaginous, saccharin and starchy foods; the nutrition of the patient should be maintained by stomach digestion, rectal alimentation and absorption of the skin. The remedies indicated are those which control reflex irritation and intestinal germicids. If there exists anemia of the nerve centers of the brain, it should be relieved by such tonics as nux vomica, strychnia, arsenic; if general or local hyperemias, by bromids. If tonics are indicated, the hyposulphates of lime, soda and potassa, or the bitter tonics. The iron preparations are injurious. In cases of diabetes mellitus add to the general treatment from 15 to 20 grains of bicarb. of potassa after each meal. Purgatives should be avoided, except those that act on the large intestine. These should be alternated with enemas.

DISCUSSION.

Dr. BORDMAN REED of Atlantic City, N. J.—Up to this time I had not been led to believe that there were as many reflexes from the duodenum as my friend Dr. Allen has given us to understand he has found. I should be inclined to question whether all of his cases were true reflexes, and also whether they came from disease limited to the duodenum. I should be strongly inclined to think that most of the cases he has reported were cases of intestinal toxemia from inflammation of the small intestine. In fact, it is very difficult to differentiate disease limited to the duodenum. The duodenum is a very small portion of the intestine, and its structure is very similar to that of the small intestine below, so that I can not understand how Dr. Allen can be certain the disease was limited to that short distance. The great burthen of evidence from other sources would lead us to believe that the results were more from toxemia, the absorption of various toxins, than from reflexes. However, I am inclined to believe that there are also reflexes from that region. I think we are apt to take too narrow a view of disease. Haig, in his famous book on uric acid, attributes nervous diseases to uric acid causes. On the other hand, Bouchard attributes them to toxemias, and others to other things. I think it probable that all of these agents are concerned in the production of nervous diseases.

Other authorities have differed somewhat from Dr. Allen with regard to the relative frequency of diseases of the stomach and intestine, particularly with regard to ulcer. Andral reported the proportion of ulcers in the duodenum and stomach as 1 to 40. Another author gives 1 to 9. Ordinary round ulcer is much more frequent in the stomach than in the duodenum. The duodenum is also liable to the catarrhal type of ulcer, but the usual kind is the round ulcer due to an excess of acid passing down from the stomach. My own studies and experiments on the acidity of the gastric juice have shown me that a great deal of nervous disease is attributable to an excess of hydrochloric acid in the stomach. The excess of acid may pass into the duodenum and produce irritation, sometimes ulcer, and probably sometimes catarrhal disease. It is a large subject. We should welcome contributions from every quarter, but not be dogmatic in our conclusions.

Dr. ALLEN—The anatomic, physiologic and pathologic points made by me in my paper have not been objected to by my friend Dr. Reed. He objects to the relative frequency of gastric inflammatory processes and those of the duodenum. Answering, I would say that wherever there did exist a question of doubt requiring differential diagnosis between these diseases, the stomach in each case was washed out and its contents thoroughly examined, chemically and microscopically, for the débris of inflammatory processes, which protected me from any possible mistake. The same care was taken in the investigation of the possibilities of the existence of inflammatory diseases below the duodenum, and they were not found. The statement of Dr. Reed that I am not supported by the literature on the subject is true, but he must bear in mind that the literature on the subject is so very meager that I am justified in concluding that investigators have overlooked this very important portion of the alimentary canal. The Doctor attempts to explain some of the phenomena attending these cases by the absorption of toxins. As toxins are never absorbed by normal structure, but only where there are inflammatory processes, there might be a question of doubt as between the causes which produce the phenomena of the cases reported by me. The phenomena themselves can not be explained by the Doctor's theory, but can scientifically be explained by reflex irritation.

DIAGNOSIS OF ASCITES.

Presented to the Section on Practice of Medicine at the Forty-eighth Annual Meeting of the American Medical Association at Philadelphia, Pa., June 1-4, 1897.

BY JAMES TYSON, M.D.

PHILADEAPHIA, PA.

The object of this brief communication is to call attention to a symptom which I think has hardly received sufficient attention at the hands of clinicians and which I know to have been misinterpreted. I allude to tympany in the flanks and its significance in the diagnosis of ascites. It is generally taught that the *absence* of tympany in the flanks is characteristic of ascites; while its presence can not be regarded as consistent with any considerable degree of accumulation of liquid in this region. A case now in my wards at the Hospital of the University of Pennsylvania illustrates the possibility of error arising from a too strict adherence tothis guide. A woman, aged 37 years, was admitted with mitral stenosis and insufficiency, with passive congestion, enlargement and tenderness of the liver, ascites and general anasarca. When lying on her back the lower abdomen was somewhat bulging, and over this region and laterally on both sides as far as a vertical line drawn through the anterior superior spinous process of the ilium, distinct fluctuation and a succussion wave could be elicited. Behind this, distinct tympany could be brought out by percussion in both flanks. It was usually more marked on the right side. So marked was the tympany, and so much in contrast with what seemed usual that experienced men who saw her thought that the condition could not be ordinary ascites but must be a collection of fluid, circumscribed by adhesions. A trocar was introduced and seven pints of clear serum drawn off, such as constitutes an ordinary ascites, emptying the abdomen completely of fluid. As the fluid reaccumulated, the original signs appeared and were followed by another tapping, when an equal amount of fluid was drawn off. This was repeated several times.

Having had this experience with the patient referred to, I proceeded to examine carefully every case of ascites I met in the wards, and in quite a number I could bring out, by percussion, an area of tympany located as described. It varied in extent and distinctness, and in no case was it as marked as in the woman referred to. It was, however, easily recognizable, though not always in each flank, sometimes being more marked in one and sometimes in another, while it was sometimes present in one and absent in another.

I then proceeded to examine the text-books available and found more frequent allusion to it than I had expected. Thus, in Leube's "Specielle Diagnose der Inneren Krankheiten," vol. i, p. 381, 4th ed., occurs the following: "So kann man unter percutirend neben der Niere nach der Linea axillaris hin, einen schmalen Streifen tympanitischen Schalls finden. Es rührt dies davon her, dass das Colon ascendens und descendens in ihrem hinteren Umfang vom Peritoneum nicht überzogen sind, und deswegen hier kein Transudat liegen kann," *i.e.*, by percussing from the neighborhood of the kidney downward in the axillary line a narrow zone of tympany may be found. This is because the posterior portions of the ascending and descending colon are uncovered by peritoneum in this situation, and on this account no transudate can lie there).

Passing to Strümpell, second American edition 1893, p. 462, I find "the resonance on percussion of the deepest and most dependent portions of the abdomen may be misleading in this way, that *even in ascites* a narrow zone may be tympanitic. This should be remembered."

Turning to American text-books, Da Costa, eighth edition, p. 712, quotes Bacelli that "in ascites there is a deep tympanitic sound during percussion in the region of the intestines, while an ovarian cyst presents dulness on the side in which the cyst has its origin, and a tympanitic sound on percussion on the other." I can not discover that reference is intended to the point to which I allude. In John H. Musser's new work on "Medical Diagnosis," I find no allusion to it, nor in James T. Whittaker's recent "Theory and Practice of Medicine." I find in Osler, p. 508, second edition, the usual statement, viz.: "In the dorsal position, with a moderate quantity of fluid in the peritoneum, *the flanks are dull*, while the umbilical and epigastric regions into which the intestines float are tympanitic." No mention is made of occasional tympany in the flanks.

Wood and Fitz on page 969 of their recent text-book say, "if the intestines contain no gas, or are adherent to the abdominal wall or the mesentery is so short or the quantity of fluid so large that they are prevented from floating to the surface, the dulness is no longer characteristic; but the resonance of the intestines may be found in the lower abdomen *or in the flanks*, in either of which places it may remain even if the patient changes his position." The fact is here pointedly stated, but its connection by a semicolon, with what precedes, would seem to refer it to an unusual condition of the small intestine rather than with the constant situation of the ascending and descending colon. In his article on "Ascites," in Pepper's "American Text-book of Medicine," Dr. Fitz makes practically the same statement.

Dr. Henry M. Lyman expresses the fact much more directly than any other American author, for on page 411 of his recent text-book he says: "If the intestinal canal be free from fecal contents, the region of the cecum and the descending colon will emit a tympanitic sound on percussion, even though the adjacent regions are occupied by dropsical fluid." This is precisely correct.

Of the older but still comparatively recent authors of text-books, Austin Flint, Sr., Henry's edition 1894, p. 530, says: "The exceptional cases in which this test afforded by percussion is not available, are those in which the intestinal coils are fixed by morbid adhesions. This is rare in a case of purely dropsical effusion."

In neither Roberts Bartholow's, Alfred Loomis's or Frederick T. Roberts's text-books do I find the fact referred to. C. Hilton Fagge, on page 309, vol. ii, (American Ed., 1886), says: "Again, when in ascites the border of the dull region is percussed freely, the left hand finger being pressed backward as much as possible, one can often detect a resonant note from the presence of intestine beneath."

Niemeyer (Humphreys' and Hackley's Translation, N. Y., 1870, p. 623), has an interesting paragraph, as follows: "Bamberger advises us to pay particular attention to the spot between the crest of the ilium and the twelfth rib, for in ovarian tumors at that point we generally find the full sound of the larger intestine; in ascites we do not. *Still he acknowledges that this sign occasionally fails.*" Now this is precisely the situation in which the tympany in ascites is occasionally met.

My own book contains a somewhat bungling allusion to it, heightened by a typographical error. On page 386 will be found the following: "There are also two sites posteriorly where a tympanitic note may be produced by percussion, viz., upward (should be *downward*) from the neighborhood of the kidney on each side behind the mid-axillary line, because in this situation in the ascending and descending portions of the colon with the posterior portions uncovered by peritoneum, and therefore inaccessible to the fluid." Evidently in writing this I did not realize the actual facts or I would have made it clearer in the text, though the understanding is quite different if instead of the word "upward" we read "downward." I had evidently read the paragraph in v. Leube without having realized the condition itself. Since I have studied it my notions are clearer and more definite, and it seemed to me worth while to take an opportunity to call attention to the subject and impress it by the models of Steirges after sections of the frozen cadaver, here exhibited, in which the portions of the colon thus exposed are clearly seen. It is to be remembered that the condition is also influenced by various degrees of distension of the colon as well as by the quantity of ascitic liquid.

DISCUSSION.

Dr. Rochester of Buffalo—I was puzzled this winter by a case in the hospital. There was distinct tympany in the right, and slight tympany in the left flank. I tapped and removed fluid.

Dr. Herman B. Allyn of Philadelphia- -I have a case in the hospital now which presents this condition of tympany in the flank. I still thought fluid was present, and on tapping withdrew several pints, but, on reaccumulation of the fluid, tympany did not occur. It would seem that it may sometimes exist, while at other times it may not or that it may be a temporary condition.

Dr. Tyson—I rise to confirm what Dr. Allyn says. We found considerable variation in the amount of this tympany at different times and previous to successive tappings. One flank was almost always more tympanitic than the other. It goes without saying that the quantity of fluid makes some difference. You can understand that if there is a large quantity of fluid in the peritoneum pressing upon the colon, there will be less tympany from the colon than in cases in which there is less compression. But I have observed the tympany in large abdominal effusions.

A FURTHER REPORT ON ISCHOCHYMIA (DILATATION OF THE STOMACH).

Presented to the Section on Practice of Medicine, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY MAX EINHORN, M.D.
NEW YORK, N. Y.

The President of our ASSOCIATION, Dr. Nicholas Senn, was the first in this country to direct the attention of the profession to the importance of surgical interference in cases of stenosis of the pylorus. In 1891 Senn published in the *Medical Record* (November 7 and 14) fifteen cases of pyloric stenosis, two of a benignant type and thirteen due to malignant disease (cancer), on which he had operated. In the two cases of benignant stricture the operation consisted in Heinecke-Mikulicz pyloroplasty. In the remaining thirteen, of cancer of the pylorus, gastro-enterostomy was established. In this paper Senn said: "Stricture of the pylorus is a surgical affection and should be treated as such with the same right and for the same reasons as a stricture of the esophagus, rectum or urethra. Reliance on medicine is as deceptive and useless in these cases as in the treatment of stricture of any other organ. Permanent relief can only be secured by prompt surgical interference."

In November, 1894, I[1] read a paper before the German Medical Society of New York on the "Diagnosis and Treatment of Stenosis of the Pylorus." In this address I gave my own experience regarding this condition and suggested the name of "ischochymia" in place of "gastrectasis," "dilatation of the stomach," or "gastric insufficiency of the second degree" (Boas), as being more suitable. This term was intended to convey the idea that stagnation of the food in the stomach is the principal symptom of this affection, and that the abnormal size of the organ is of secondary importance. In this paper I reported four cases of a benignant stricture of the pylorus, in which operations (either pyloroplasty, pylorectomy, or gastro-enterostomy) had been successfully performed, and several cases of malignant stenosis of the pylorus, in which gastro-enterostomy has also proved temporarily beneficial.

Among the more recent literature the paper of Pepper and Stengel[2] on "Dilatation of the Stomach," is noteworthy. These two authors describe all methods which serve to determine the size and capacity of the stomach, but sufficient weight is not placed on the most important symptom—the stagnation of food. This work contains an abundance of casuistic material and is highly meritorious.

Recently I read a paper embodying my additional observations on ischochymia, before the Society of Physicians of the German Dispensary of New York (April 22, 1897). As this affection is of quite frequent occurrence and of great importance to the clinician, as well as to the surgeon, I present a summary of my own experience.

The cases of ischochymia which have been under my treatment may advantageously be divided into the following groups:

1. Cases of ischochymia submitted to operation.
    a. Benign stenosis of the pylorus.
    b. Malignant stenosis of the pylorus.
2. Cases of ischochymia treated by palliative measures.
    a. Benign stenosis of the pylorus.
    b. Duodenal stenosis.
    c. Probably pure atony of the stomach.
    d. Malignant stenosis of the pylorus.

The cases of ischochymia from benign pyloric stenosis submitted to operation comprise ten, of which I shall describe one:

Case 1.—Nov. 29, 1896, A. L., 32 years old, manufacturer, has suffered more or less from pyrosis since his eighteenth year. The appetite was always poor, and the patient was regarded as a small eater; he was troubled with frequent eructations, and was always constipated. During the last two years he has complained constantly of a burning feeling in the epigastrium two hours after meals; the ingestion of food, as well as the administration of bicarbonate of soda, alleviated this symptom for a short time. Four months ago the patient began to experience colicky pains in his upper abdominal region; these usually appeared five to six hours after eating or later at night, especially when he had neglected to take anything for the burning. The appetite was not much changed, sometimes somewhat slighter than previously. Vomiting only occurred infrequently after gastric lavage had been undertaken. The patient stated that on one occasion after washing out the stomach a small quantity of blood was noticed.

Status praesens: Patient is fairly well nourished; color somewhat pale; tongue slightly coated. Thoracic organs normal. Palpation of the abdomen reveals no areas sensitive to pressure. Splashing sound present, and the stomach can be traced to a line one or two fingers' breadth beneath the umbilicus. Peristaltic contractions are not visible. The urine contains neither sugar nor albumin, and is secreted in sufficient quantity.

Nov. 29, 1896. Examination of the stomach in the fasting state reveals a considerable amount of chyme (200/c.c.), consisting chiefly of bread and starchy substances. HCl+, acidity = 48.

November 30. Examination of the stomach one hour after Ewald's test-breakfast: Quantity equals 300 c.c.; HCl+, acidity = 76; slight residue of food from the previous day can be recognized.

December 1. Examination in a fasting condition furnishes a greenish fluid containing a few fine particles of food and of strong HCl reaction.

Deccember 3. Contents obtained in a fasting condition consist of fluid mixed with bile and brownish masses containing only a few food particles. After lavage blackish masses finally appear. The slight stagnation of foods at once awakened the suspicion of a pyloric stenosis of moderate degree, and the brownish masses (altered blood) pointed to the existence of an ulcer in the vicinity of the pylorus. This suspicion was further confirmed by the circumstance that on December 18, 400 c.c. of fluid, containing numerous brownish masses, were obtained from the fasting stomach; at the same time an area of sensitiveness to pressure was present in the epigastrium, especially toward the right side. The patient was now put in bed and a strict cure initiated for the ulcer. From December 18 to 23 he was nourished per rectum, after which small quantities of milk were administered *per os.*

Jan. 2, 1897. Lavage in the fasting state showed the presence of a slight amount of food residue (100 c.c. of chyme mixed with bile); the same condition was noted on January 8.

The diagnosis previously made of a commencing benign pyloric stenosis complicated with ulcer in the vicinity of the pylorus, was now assumed, with greater certainty, in view of the futility of the treatment, and the patient was urgently advised to undergo an operation, the more so since all therapeutic measures had proved unavailable.

The operation was performed by Dr. F. Lange on Jan. 13, 1897. There was found an ulcer on the anterior side of the stomach, closely adjacent to the pylorus; the latter was markedly thickened (rigid) and its lumen narrowed. The ulcer was excised and the pyloroplastic operation of Heinecke-Mikulicz practiced. The mucous membrane of the stomach was markedly swollen and hypertrophied.

The patient rapidly recovered from the operation and has since completely recuperated; he is free from all disturbances and has gained *twenty-five pounds in weight.*

On reviewing my cases of benign stenosis, I find that the diagnosis of ischochymia and of the conditions which give rise to it (pyloric stenosis, ulcers in the immediate vicinity of, or in the pylorus) can be made with a fair approximation to certainty. In all the ten cases operated on, the diagnosis was completely confirmed by the conditions revealed at the operation.

---

[1] Max Einhorn: Medical Record, Jan. 19, 1895.

[2] Pepper and Stengel: The American Journal of Medical Sciences, Jan., 1897, p. 34.

Of these ten cases, eight were cured and two terminated fatally in consequence of shock and cardiac failure shortly after the operation. The latter, however, sought surgical intervention at too late a period, and there can be no doubt but that this was the sole cause of the fatal termination. Of the remaining eight, seven have been completely cured, that is, the patients are able to eat everything without any disturbances and are completely well. One of the patients has been improved, but not completely cured, that is, she continues to suffer now and then from pains which result from cicatrices at the lesser curvature, yet she is able to partake of a more varied diet without the occurrence of a stagnation of gastric contents.

In some of the cases of malignant stenosis of the pylorus I was able to make the diagnosis even in the absence of tumor and also of lactic acid in the stomach, and my experience leads me to conclude that gastro-enterostomy exerts a beneficial, although temporary, effect in this condition. The majority of these patients who have survived this operation gain in weight and pass a much more comfortable existence than could be afforded them by any other measures.

In the cases of ischochymia dependent upon a benign stenosis of the pylorus, or upon a relaxation of the muscular layer of the stomach, improvement could quite frequently be obtained by palliative measures (group 2). This change for the better means that in relaxation of the gastric muscularis, the latter, under appropriate treatment, recuperates and becomes more vigorous, while in stenosis of the pylorus a kind of compensation of the stomach occurs, that is, the organ acts with greater energy, so as to be able to perform its functions notwithstanding the obstruction existing at the pylorus. It can therefore be readily seen that an improvement as a result of palliative treatment can be expected only in cases in which the pyloric stenosis is not very marked; moreover, it is also clear that in the event of improvement from palliative measures we must always be prepared for a return of the ischochymia.

If the symptoms of ischochymia do not yield to medical treatment, surgical intervention is urgently called for, because otherwise a fatal outcome may readily take place. Thus I have observed two instances in which death occurred from starvation.

I will now discuss the chief points relating to the diagnosis and therapeutics of ischochymia.

Diagnosis.—The salient points in the diagnosis of ischochymia is the presence of food residue in the stomach in the morning in the fasting condition, the patient having taken a substantial meal on the previous evening. If this symptom is found to persist for a long time, we have to deal with a serious affection, and it will now be necessary to determine whether this consists in a relaxation of the gastric muscular coat or a narrowing of the pylorus; in the latter case it is further requisite to decide whether a benign or malignant process be present.

The differential diagnostic points which demand consideration are well known to you. It appears to me of importance to analyze the diagnostic significance of some of the symptoms, which, when present, are very valuable, but whose absence does not militate against the existence of pyloric stenosis. These symptoms are:

1. The dilated or abnormally large stomach.
2. The thickened and readily palpable pylorus.
3. The peristaltic restlessness of the stomach.
4. The fermentation products.

1. The abnormal size of the stomach is pathognomonic only if the organ occupies nearly the entire lower section of the abdomen and contains over three to four liters of fluid. Such stomachs are frequently met with in old cases of stenosis of the pylorus and their presence at once awakens the suspicion of a narrowing of the pylorus; before this diagnosis can be made, however, the presence of ischochymia must be determined. In this country considerable weight has been placed on this symptom, as we find in the above-cited article of Pepper-Stengel; yet the absence of this diagnostic sign should not lead us astray. For it is our aim to make the diagnosis of pyloric stenosis as early as possible, while the pronounced, at once perceptible dilatation of the stomach requires some time for its development. Hence, it is not advantageous to apply the old name of "gastrectasia" to designate the entire condition, but to employ instead the term "ischochymia," because this is the most important and at the same time the earliest symptom.

2. If it is possible by means of palpation to map out the pylorus as a smooth oval tumor, and if ischochymia be present and the disease has lasted over one and a half to two years, we can with certainty make a diagnosis of benign pyloric stenosis. Among the cases of this affection observed by me, this symptom was found quite often.

3. Peristaltic restlessness of the stomach was found in two of the operated cases of benign stenosis of the pylorus, and in nearly all of the non-operated cases of this disease. Inasmuch as peristaltic restlessness of the stomach but very rarely occurs as a pure neurosis, this symptom is of great significance for the recognition of stricture of the pylorus, the more so as an examination for this purpose (simple inspection of the abdomen in the recumbent position) is unattended with any difficulty.

The presence of this symptom in connection with the existence of ischochymia, speaks in favor of narrowing of the pylorus, and against simple relaxation of the gastric muscular coat; the absence of this sympton is of no consequence.

4. Fermentation products (formation of lactic acid or gases in the stomach) are observed almost constantly in all cases of ischochymia. Commonly, one or the other kind of fermentation is present, that is, either formation of lactic acid or formation of gases. The lactic acid is found in the stomach in cases where the secretion of hydrochloric acid is considerably diminished, while the development of gas is encountered in cases in which there is an abundant secretion of gastric juice. These points, which have been especially emphasized by H. Strauss[3], I can completely confirm on the ground of my own experience. These fermentation products may be absent, however, notwithstanding the presence of pyloric stenosis, if the proper treatment has been adopted, that is, if the stomach has been washed out several times.

The constant or frequent occurrence of small quantities of bile in the stomach does not in my experience militate against the existence of a narrowing of the pylorus; on the other hand, it appears to me to point to a firm rigidity of this orifice, in consequence of which the latter is never completely closed.

---

[3] H. Strauss: Zeitschr. f. klin. Medecin.

Among the more recent auxiliary measures which are available in arriving at a diagnosis, the gastroscope has been recently employed by Rosenheim and Kelling. In my opinion, there is no doubt but that this instrument has a promising future, although at present it has not as yet been generally utilized.

Treatment.—In the treatment of ischochymia it is necessary first of all to ascertain the cause of the stagnation of food in the stomach. If this be due to a far advanced benign stenosis of the pylorus, or to a commencing occlusion of this opening of malignant nature, surgical interference (pyloroplastic operation, pylorectomy, or gastro-enterostomy) is indicated. If we have to deal, however, with commencing benign stenosis of the pylorus, or a genuine relaxation of the muscular coat of the stomach, palliative treatment should first be given a trial, while in the event of its failure an operation is demanded.

The palliative treatment in the milder cases consists in the employment of a fluid or semi-fluid diet (milk, soups with finely ground farina, meat broths with egg, egg and milk), lavage of the stomach in the fasting condition, followed by spraying with a one per mille solution of nitrate of silver, and in the administration of medicaments which prevent fermentation. Among these may be used benzonaphthol, salol, bismuth and resorcin. 1 frequently give

Resorcin.	4.0
Bismuth, subnitr	20.0
Aq. dest.	200.0

S. One tablespoonful in a wineglassful of water, three times daily, half an hour before meals.

In severe cases (frequent vomiting, frequent pains, intense burning sensations) it is advisable to keep the patients in bed for about three weeks and to nourish them for five days exclusively per rectum, and then slowly and gradually adopt a milk diet, as in ulcer of the stomach—in this condition, however, much more cautiously and slowly.

Thus, for example, on the sixth day I give only two tablespoonfuls of milk every hour, on the seventh day three tablespoonfuls, on the eighth day four tablespoonfuls, etc., until I have reached 100 c.c. every hour; then I give 200 c.c. every two hours, and increase to 300 c.c. On every other morning I determine by washing out the stomach, in the fasting condition, whether it is empty.

In this manner it is quite frequently possible to adapt the stomach, first to a light and later to a heavier diet. The patients then increase gradually in weight and appear completely well. Yet they can not be regarded as entirely healthy, because we must be constantly prepared for a recurrence of the old affection.

Moreover, in cases where it is not possible to remove the ischochymia by palliative measures, the patient may sometimes maintain a comfortable existence under the sytematic use of washings out of the stomach and the maintenance of a light and rather fluid diet. Such patients, however, are menaced by many dangers and can enjoy but few of the luxuries of life, and for this reason the clinician should insist that an operation is to be regarded as the only correct procedure.

In summarizing this article the following conclusions can be formulated:

1. In the vast majority of cases of prolonged disturbances in the transportation of chyme from the stomach into the intestine, a narrowing of the pylorus exists.

2. The earliest, and at the same time most important, sign of pyloric stenosis is ischochymia; the dilatation of the stomach which is met with here, and which is often so considerable, does not develop until later, and besides, may in exceptional cases occur in the presence of an adequate prochoresis.

3. Ischochymia produced by a malignant neoplasm at the pylorus always demands an operative treatment (gastro-enterostomy, eventually pylorectomy).

4. In cases of ischochymia dependent upon a commencing benignant pyloric stenosis (or ulcer in the vicinity of this orifice) or a relaxation of the muscular coat of the stomach, an effort should first be made to afford relief by palliative measures; if this is not successful, then a pyloroplastic operation or gastro-enterostomy should be performed.

5. Ischochymia due to a benign markedly developed narrowing of the pylorus (in these cases the pylorus can usually be felt as a small tumor) demands early resort to operation (pyloroplastic procedures, if the stricture is not too small and if the adhesions are not too numerous, otherwise gastro-enterostomy).

DISCUSSION.

Dr. BOARDMAN REED of Atlantic City, N. J.—I would ask the author with regard to diet, whether he recommended milk? I had been led to believe that milk is unsuitable in dilatation of the stomach, on account of the difficulty of giving enough without distending the stomach. Most German authorities take that view. I would also ask whether he means that milk should be the sole diet.

Dr. EINHORN—Of late it has been found that a liquid or a semi-liquid diet is suitable for this condition, especially in those cases in which there is suspected stenosis of the pylorus, for thicker substances do not pass through. In dilatation of the stomach, with weakness of the muscle of the stomach, not due to stenosis of the pylorus, there may be a question whether to nourish the patient by liquid or by more consistent food. But even there, if we give small quantities of liquid at a time, I think we can achieve more than by suddenly cutting them off.

A BRIEF CONTRIBUTION TO THE BIOLOGY OF THE MALARIAL PARASITE.

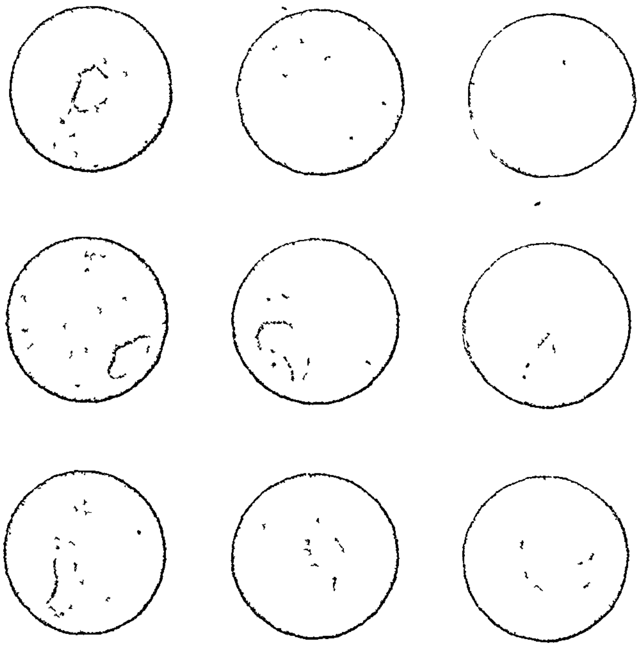
BY R. S. WOODSON, M.D., U. S. ARMY.
NEW ORLEANS, LA.

The biology of the malarial parasite is one of the most interesting subjects in modern medicine, the accurate understanding of which is rendered exceedingly difficult to the average practitioner by reason of the conflicting opinions of competent observers as to its life cycle, the function of its various forms and their pathogenic relationship to the various clinical malarial manifestations. The segmentation of the intra-corpuscular parasites, their escape into the plasma of the blood and their reappearance as fresh hyaline bodies in the red corpuscles as described by Golgi, is believed to be the method of reproduction. The evidence that this is the method of reproduction rests upon the very great resemblance between the antecedent and resultant hyaline bodies, and further upon their identity with the fresh hyaline forms that make their appearance just at this time in other red blood corpuscles.

This theory of reproduction is rendered somewhat hypothetic by the absence of visual confirmation. The fact that free hyaline bodies are rarely seen in the peripheral blood and reproductive changes probably take place exclusively in internal organs, would account for the failure on the part of the various investigators to observe the entrance of the hyaline form into the normal red corpuscle.

By fortuitous accident rather than systematic observation in the routine examination of malarial blood of patients admitted to the Post Hospital, Jackson Barracks, the writer believes he has observed this missing link in the life cycle of the malarial parasite.

Upon examining a specimen of blood, taken with aseptic precautions from lobe of left ear of Private G. F., U. S. Army, who was suffering from malarial fever, intermittent, tertian (time of examination being several hours before paroxysm), the following phenomenon was observed: Field moderately filled with red blood corpuscles, a clear space in center, across this space a round hyaline body, one-fifth size red corpuscle, was seen moving; whether by reason of its own inherent motility or in obedience to the laws of gravitation was not determined. It was seen to attach itself to a perfectly normal red blood corpuscle and appeared to enter the same, for its outline became less distinct. Further, it acquired ameboid movement and was seen to move about in the protoplasm of the cell, as well as to assume alterations of outline and slight increase in growth, as shown in the accompanying drawings. The parasite after its entrance into the corpuscle was observed by my assistant, Hospital Steward Cleaver, and myself, for two hours, and from its behavior and appearance during this time I feel convinced that we were observing an ameboid hyaline intracellular form of the malarial plasmodium.



Jackson Barracks.

RELATION OF FAT NECROSIS TO THE PANCREAS.

Presented to the Section on Practice of Medicine, at the Forty-eighth Annual Meeting of the American Medical Association, at Philadelphia, Pa., June 1-4, 1897.

BY HERBERT U. WILLIAMS, M.D.
PATHOLOGICAL LABORATORY OF THE UNIVERSITY OF BUFFALO, BUFFALO, N. Y.

As pancreatitis with fat necrosis is not a very common disease I give in the first place an outline of our knowledge concerning it.

The patients are almost exclusively adults. A history of gastro-intestinal disorder dating back for a considerable period is frequently given. Fitz describes the *symptoms* of acute pancreatitis as follows: "Sudden, severe, often intense epigastric pain, without obvious cause, in most cases followed by nausea, vomiting, sensitiveness and tympanitic swelling of the epigastrium. There is prostration, often extreme, frequent collapse, low fever, with a feeble pulse. Obstinate constipation for several days is the rule, but diarrhea sometimes occurs." The affection is usually fatal.

The symptoms therefore are vague and not very characteristic. The disease has been mistaken for intestinal obstruction, and has been confused with appendicitis. However, a correct antemortem diagnosis has been made more than once. The nature of the affection is not generally revealed until the autopsy is performed.

Autopsies on these cases have shown a remarkable uniformity in their findings. The pancreas is either swollen and infiltrated with blood which may have escaped into the adjacent tissue; or it is dark and necrotic. It is frequently separated from its connections by softening of the neighboring necrotic tissue; such a condition of necrosis is generally called sequestration of the pancreas. Accompanying the lesion of the pancreas in a large proportion of cases one finds a striking alteration of the adipose tissues, which is termed fat necrosis. Opaque, white or gray nodules of a soft chalky consistency, reaching the size of a pea or even larger, are seen scattered through the otherwise yellow and translucent fat. They appear in the adipose tissue on the surface of the pancreas and in its vicinity. Confluence and softening of the nodules probably assist in producing sequestration of the pancreas. Similar nodules may be met with in the adipose tissue about the peritoneal cavity at points remote from the pancreas, as in the omentum and mesentery. This condition is termed disseminated or multiple fat necrosis. They are rarely seen in parts not in contact with the peritoneum, but have been observed in the pericardial and subcutaneous fat. Peritonitis is not usually present. Among forty-seven reports of cases of disseminated fat necrosis, in which I could find that the general condition of the body was specified, thirty-five (about 75 per cent.) were described as being fat, frequently as very fat indeed. Among fifty-three cases of disseminated fat necrosis of which I have collected descriptions there were six in which no pancreatic disease was demonstrated.

Pancreatic hemorrhage. .	6
Hemorrhagic pancreatitis. .	18
Gangrenous pancreatitis	15
Suppurative pancreatitis	6
Chronic pancreatic disease	2
No pancreatic disease.	6
Total.	53

Fat necrosis occurs also in connection with suppurative pancreatitis, but less frequently than with the hemorrhagic and gangrenous forms. Curiously enough, it seems only occasionally to have been observed accompanying carcinoma of the pancreas or the conditions leading to obstruction of its duct.

The nodules mentioned appear, under the microscope, to be surrounded by a zone of inflammatory reaction, sometimes with hemorrhages. They are made up of needle-shaped crystals, opaque bodies which may be as large as fat cells, oil globules and amorphous material. The outline of fat cells, but not their nuclei, can generally be detected within them, indicating that the change consists in an alteration of these cells and their contents. This justifies the name fat necrosis. Chemical analyses show that the change depends upon a decomposition of the neutral oils, which are the normal contents of the fat cells, liberating fatty acids and glycerin. The fatty acids may combine with some of the bases present in the lymph, generally calcium, to form soaps.

As an additional proof of the intimate relation between the alteration of the fat cells and some function of the pancreas, it has been asserted that subjects dying of affections having nothing to do with the pancreas, often exhibit a few small areas of fat necrosis in the adipose tissue about the pancreas or between its lobules. Balser found such areas in 20 per cent. of twenty-five cases examined by him. R. Langerhans recorded a similar observation for 14 per cent. of twenty-eight cases. From paragraphs in the text-books of Ziegler and Weichselbaum, and from remarks of Fitz, Thayer and others, one is led to infer that experiences of this sort are matters of common occurrence. On the other hand, Kasahara encountered fat necrosis in but one of eighty-three pancreases studied by him. I have inspected the pancreas carefully and cut it in thin slices in seventy-four subjects free from pancreatic disease, and have met with but two examples of fat necrosis. In each there was a single small nodule. R. Langerhans has suggested that the alteration may be a postmortem phenomenon, due to the action of the pancreatic juice. In one of my two cases I believe that to have been probable. In the other the change must have occurred before death, as a distinct inflammatory reaction was visible about the nodule.

Furthermore, Balser has described fat necrosis as being often present in the adipose tissue of the hog's pancreas. He found it in this situation in nearly all Hungarian and many Algerian hogs; but less frequently in German hogs. Never having seen any observations in this direction recorded concerning American swine and having been informed by Dr. Salmon of the Bureau of Animal Industry that he knew of none, I examined the pancreases of a hundred hogs. They were studied while they were fresh and were cut in thin slices with a razor. Among these hundred specimens two were found that exhibited fat necrosis in the interlobular fat. In one there were many areas; in the other only a few. These observations may be interesting on account of establishing still more closely the connection between the process in question and the pancreas.

Occasionally fat necrosis has been observed, as for instance in lipomata, in situations where no suspicion of any relation with the pancreas could be entertained. I have several times met with what appears to be the same change in the adipose tissues of the cat in trifling degrees, but not near the pancreas.

Numerous cases of pancreatitis and disseminated fat necrosis have been studied from the standpoint of bacteriology and several varieties of bacteria have been isolated from them. The bacillus *coli communis* has been found much more frequently than any other form. Its claims to being an important etiologic factor have been seriously considered by some writers. However, nothing has been definitely proven in this direction. In some instances, where the necrotic nodules have been examined, they have been found to be sterile. Hlava injected various bacteria into the pancreas of a number of cats, dogs and rabbits after laparotomy. With the diphtheria bacillus he succeeded in exciting a hemorrhagic pancreatitis with fat necrosis in the cat. His experiment would seem to render doubtful a specific action on the part of any particular organism. This view seems to me to receive confirmation from an observation of mine upon a cat in which a peritonitis due to a micrococcus infection was accidentally produced. The infection spread to the pancreas, leading to pancreatitis and fat necrosis.

An interesting theory to explain the causation of fat necrosis was proposed by Rolleston. This theory refers it to a disturbance of innervation arising in the solar plexus. I am not aware of any work based on pathologic anatomy or experiment in support of it.

Several years ago R. Langerhans suggested that, as the pancreas elaborated a ferment capable of decomposing neutral fats, liberating their fatty acids, this ferment might be responsible for the peculiar change that takes place in fat necrosis. His theory seems plausible, remembering the constant association of that condition with the pancreas that has been mentioned. Langerhans succeeded in producing an area of fat necrosis in a rabbit by injecting an extract of the pancreas of another rabbit into the adipose tissue. This was the only successful one among twelve experiments. His work, furthermore, is open to the objection that bacterial contamination was not with certainty excluded.

Dr. Whitney of the Harvard Medical School placed a ligature about the pancreas in a number of dogs and obtained fat necrosis in one of them. His results have never been published.

Hildebrand and his student, Dettmar, placed a ligature about the gastro-splenic portion of the pancreas in two cats to prevent the discharge of its secretion through the duct; and in six others they performed the same operation and also ligated the veins leaving the organ. In all cases fat necrosis was found about the pancreas. They were also successful in producing it three times by introducing portions of the pancreas of one cat into the abdominal cavity of another. In one instance they obtained it after removing a piece from the organ and leaving the distal portion without ligature. Hildebrand, furthermore, injected pure trypsin into the abdominal cavity and found that hemorrhages into the peritoneum resulted. He suggested that the hemorrhages so frequent in pancreatic affections might be due to trypsin while the fat-splitting ferment was responsible for the change in the adipose tissues.

Rosenbach and his pupil, Jung, with a similar object in view, introduced trypsin and at other times portions of pancreas into the abdominal cavities of rabbits. Out of four trials with pieces of pancreas, they obtained fat necrosis once, using dog's pancreas. On the other hand, Senn, in a series of experiments reported some years ago, found the pancreatic juice innocuous when it came in contact with the peritoneal tissues.

As the results of Hildebrand's work seemed of great importance, I attempted to verify them. Two dogs, one rabbit and seventeen cats were operated on. The cat is particularly suitable for the experiment on account of the abundant omental and retroperitoneal adipose tissue, and because of the accessibility of its pancreas. The pancreas of the cat consists of a duodenal portion, and a gastro-splenic portion, which corresponds to the principal part of the human pancreas. The gastro-splenic portion is covered throughout by peritoneum, and is easily reached. In all these animals it was surrounded, as close to the duodenum as was feasible, by a silk ligature tied tightly enough to insure closure of the duct. In about half of the cases as many as possible of the veins leaving this part of the pancreas, were also tied, and the gland was lacerated with a sharp hook passed into it beneath the peritoneum. The condition of the adipose tissues was noted to prevent mistakes occurring on account of the trifling fat necroses occasionally appearing spontaneously in the cat. The anesthetic employed was ether.

Five cats exhibited fat necrosis of a marked type. The change in the fat was characterized by a slight hardening, a dead white or a pale brown tinge, and an opacity, which was easily distinguished when the tissues were fresh and warm. The normal adipose tissue, under these circumstances, is soft, colorless, glistening, and nearly transparent. However, inflammatory collections may look extremely like fat necroses, and an examination with the microscope is always necessary. The areas of altered fat occurred, exclusively, close to the peritoneal surfaces. Sometimes they appeared at points some distance from the pancreas, as in the perirenal adipose tissue and in the mesorectum. But in all of the five cats, the same change was also present in the fat immediately about the pancreas; and in two of them it was much more intense there than elsewhere. It seemed to proceed from the pancreas as from a focal point. In one of the cats, nodules and flat areas of fat necrosis were present in large numbers in the fat about the pancreas, in the omentum, in the mesentery and mesorectum, and on the surface of the kidney. In this instance the picture was strikingly like the disseminated fat necrosis seen in man. In three of the five successful cases, an accidental infection of the peritoneum with diplococci was also discovered. The microscopic study of the nodules produced experimentally, gave the same results in the main as are found in fat necroses in man, except that the disorganization of the adipose tissues was not so far advanced. The fat cells, instead of being filled with transparent oil as in normal cells, contained fine linear crystals which produced the opacity already described. Frequently these crystals were arranged in a radial manner around the outer part of the cell, leaving a hollow in the middle. They reminded one of the hollow concretions of stone, lined by crystals, called geodes by geologists. Calcium salts were usually detected in abundance in the nodules, which suggested that the precipitated fatty acids might have combined with calcium to form soaps.

In addition to the work described, which was reported in detail in the *Boston Medical and Surgical Journal* for April 15, 1897, a new series of somewhat different operations has been begun. It may be interesting to note here, however, that in one instance a marked development of fat necrosis in the cat has been secured within twenty-four hours after the operation.

It would be premature to conclude from these experiments alone, that the fat-splitting ferment of the pancreas produces fat necrosis. However, they must be suggestive, considered in connection with the association of disseminated fat necrosis with pancreatitis, the occurrence of single fat necroses in the normal pancreas, and the finding of fat necroses about the pancreas of the hog. It is easy to watch the action of the fresh cat's pancreas upon neutral oil, which is quickly rendered acid. It requires no great stretch of the imagination to conceive of this change happening within the living body, if conditions are produced that bring the ferment in contact with adipose tissue. One may suppose the ferment to reach the tissues by way of the blood or lymph currents, or through the peritoneal cavity. It is noteworthy that the disseminated fat necroses found in man seldom appear except close to the peritoneum. In the cases reported where fat necroses were found in the subcutaneous tissues, even of the extremities, we are obliged to imagine some morbid agent working through the blood stream or by way of the nervous system. In the examples produced in the cat, none were seen in localities that could not have been reached by way of the peritoneal cavity.

In any case it is difficult to account for the peculiar nodular character of the necrotic areas seen in man, and often experimentally made in the cat. In this respect they resemble the focal necroses produced by the toxins of infectious diseases, like diphtheria and certain vegetable poisons, as was pointed out by Dr. Whitney several years ago.

If eventually proven that a pancreatic ferment produces fat necrosis it will be interesting to add another to the list of pathologic processes resulting from the action of the digestive ferments. From this point of view there would be an analogy between fat necrosis and peptic ulcer of the stomach. As peptic ulcer results from the digestion of a spot of mucous membrane whose vitality has been lowered by some preexisting morbid agency, we may find ourselves unable to account for fat necrosis by the action of the fat-splitting ferment alone.

DISCUSSION.

Dr. Dougall, Illinois—I would ask the author whether he has made an examination of the parotid gland in connection with the study of the pancreas in fat necrosis.

Dr. Blaisbrook, Washington, D. C.—I have been interested in this subject, having read a paper on it, and having examined one hundred cases postmortem with regard to this condition. I have not, however, met with any case of fat necrosis. The only cases in which I have met with disease of the pancreas have all been cases of carcinoma. One or two resembled very closely descriptions of fat necrosis, but under the microscope they were shown conclusively to be cases of carcinoma of the pancreas.

Dr. H. U. Williams—I have not paid any attention to the parotid gland in this work.

PNEUMONIA IN CHILDHOOD.

BY AUGUSTUS A. ESHNER, M.D.
PHILADELPHIA, PA.

While the symptomatology of pneumonia has been thoroughly worked out, and the disease is viewed as infectious by those most competent to judge, there remains yet some diversity of opinion as to the relations between the varieties designated respectively croupous or lobar and catarrhal or lobular. Pneumonia is no longer considered the pulmonary localization of a constitutional disorder, but rather a true inflammation of the lung, dependent, as experience has shown, upon a variety of causes. While the essential and the final cause is some low form of vegetal life, we have learned that the active bacterium is not always the same and that its mere presence is not sufficient to constitute or initiate the disease-process. On the contrary, certain conditions must have been previously fulfilled in order that the activity of the microorganism shall be expended in a specific direction.

Pneumonia in adult life differs from the same disease in childhood only by reason of physical and physiologic differences, but a comparative study of the affection as it appears at these two periods of life is not without interest and importance. Discussion of this subject is rendered especially opportune by reason of the publication recently of two valuable contributions dealing with different phases of it, the one by Schlesinger (*Archiv für Kinderheilkunde*, B. XXII, H. 3–6, p. 266), who reports in detail the results of a careful clinical analysis of 173 cases of croupous pneumonia in children observed at the Kaiser und Kaiserin Friedrich Kinderkrankenhaus at Berlin, and the other by Duerck (*Deutsches Archiv für klinische Medicin*, B. LVIII, H. 4, 5, p. 368), who deals at length with the etiology and histology of pneumonia in childhood based upon observations in forty-one cases studied in the Pathologic Institute of the University of Munich.

The 173 cases of Schlesinger occurred among a total of 10,487 under observation during a period of five and a half years, making the morbidity 1.65 per cent. (as compared with from 2 to 4 per cent. in adults). It is well known that croupous pneumonia is far less common in children than broncho-pneumonia. The former may, however, occur in earliest infancy, even the newborn not being exempt, although the disease is relatively uncommon in the first year of life. The period of greatest prevalence falls between the second and the fourth year, the frequency subsequently diminishing until the age of puberty. Boys suffer in larger number than girls (in the proportion of 110 to 63—with a morbidity of 2.2 per cent. to 1.5 per cent), as men are more commonly attacked than women. The disease selects by preference those of robust constitution, the well developed and the well nourished. In contrast with broncho-pneumonia, only a small proportion of the cases have been debilitated by previous disease, although a considerable number have already suffered from attacks of croupous pneumonia and a still larger number from measles. In adults also it has been found that an attack of croupous pneumonia appears to predispose to subsequent attacks.

The period of maximum prevalence for croupous pneumonia is almost invariably given as between March and May and that of minimum prevalence between September and November. The same relation was in a general way found to exist in the series of cases under consideration, although the largest number occurred in May and the next largest in June. No correspondence was observed between the prevalence of croupous pneumonia and that of diseases ordinarily supposed to depend upon the influence of cold, such as bronchitis and broncho-pneumonia, and no special relation was noted with regard to various meteorologic conditions.

Two types of initial fever were observed, the one being unattended with prodromes and the temperature rising to its acme within ten hours; and the other being characterized by prodromal manifestations for a day or two, the temperature then rising in two or three hours. The younger the child the higher in general was the fever and the more likely was it to be remittent or intermittent, in contrast with the continued fever of later years. Involvement of the upper l ttended with a higher temperature and ntly with continued fever than involve- e lower lobes, and involvement of the han that of the left. Gradual reduction of the temperature by lysis proved to be less common in children than it is in adults, occurring in 19 of 151 cases—12.6 per cent., as compared with from 20 to 30 per cent. Defervescence by crisis occurred in 132 cases—87.4 per cent.—oftenest on the sixth day, next in frequency on the seventh day, then on the fifth day. In more than two-thirds of the cases the crisis occurred during the night, continuing on an average from ten to sixteen hours. The reduction in temperature was often considerable—as much as from 3.1 to 3.5 degrees C.—and it was especially pronounced in the youngest children and in association with involvement of the upper lobes. In three-quarters of the cases the temperature fell on the day preceding the crisis to the neighborhood of normal, constituting a procrisis, in contradistinction to a pseudo-crisis. This occurred especially in the middle period of childhood and in association with involvement of the upper lobes and of the right lung. Following the crisis the temperature fell in a considerable proportion of cases below normal, sometimes very considerably, and continued at this level for many days. At times there occurred a secondary rise of temperature of brief duration, apart from any complication.

At the height of the disease, pulse, temperature and respiration pursued parallel curves. With the occurrence of the crisis, however, pulse and temperature declined as a rule notably, the latter in greater degree than the former, while the respiration frequently diminished gradually. Not rarely frequency of pulse and of respiration declined gradually, while uncommonly the respiratory frequency diminished suddenly, together with the temperature and pulse. After the crisis the pulse-respiration ratio was mostly 2.5 or 3 to 1, although exceptionally it reached 1.8 to 1. Excessive frequency of pulse (above 170) or of respiration (above 75), as well as marked infrequency of pulse (below 80), was rare.

The respiration in children suffering from croupous pneumonia assumes a peculiar type, being made up of a short rapid inspiration, a pause in the inspiratory position (absent only during rapid breathing) and a jerky, noisy expiration. At times the action of the heart is arrhythmic, especially during convalescence or following the crisis, though it is occasionally so also at the height of the disease and at this time is of unfavorable omen. Sometimes the heart-sounds are dull and impure and suggestive of the existence of a murmur; rarely the area of cardiac percussion-dulness is increased.

In determining the seat and extent of the morbid process it must be borne in mind that bronchial breathing may be transmitted to the ear from the diseased to the healthy side. In children the infiltration does not remain so strictly limited to the boundaries of the lobes of the lungs as in adults. Not uncommonly it invades adjacent portions of the neighboring lobe or less commonly the lung on the opposite side. More characteristic of pneumonia in childhood, however, is the limitation of the infiltration to a small portion of a single lobe. This localization occurs especially in the axillary region.

Of the 173 cases the right lung was involved alone in 96 (56 per cent.), the left lung in 66 (39 per cent.), and both together in 9 (5 per cent.); as compared with the following distribution in adults: the right lung in from 44 to 57 per cent., the left in from 28 to 43 per cent., both lungs in from 9 to 22 per cent. The left lower lobe was involved alone in 47 cases, the right lower lobe in 44, the right upper lobe in 37, the left upper lobe in 11. Isolated involvement of the upper lobes (and especially of the right upper lobe), although absolutely less common was *relatively* more common than similar involvement of the lower lobes. When more lobes than one were attacked the invasion was generally consecutive and not simultaneous and it pursued in general an ascending direction. The maximum degree of infiltration was generally reached on the fifth day and persisted for a day or two. Resolution is, as a rule, more rapid in children than in adults, taking place generally at about the time of the crisis. Complications are uncommon and such sequelæ as tuberculosis and pulmonary gangrene are rare.

The course of croupous pneumonia is quite as severe in children as in adults. The severity is most pronounced in those between the first and second years and also in those between the sixth and eighth years. Involvement of the right lung is attended with graver manifestations than involvement of the left lung, while there is little difference as related to involvement of the upper as compared with that of the lower lobes.

When a prodromal stage of two or three days precedes the onset of the disease proper this is ordinarily not marked by any special feature, but when the attack sets in abruptly it may be attended with vomiting (which occurred in 83 of 120 cases—69.1 per cent.), headache (in 26 cases—21.7 per cent.), pain in the side (in 22 cases—18.3 per cent.), delirium or diarrhea (each in 16 cases—13.3 per cent.), abdominal pain (in 13 cases—10.8 per cent.), chilliness (in 12 cases—10 per cent.), rigor (in 10 cases—8.3 per cent., as compared with from 80 to 92 per cent. in adults). Convulsions are relatively uncommon (in 5 cases—2.5 per cent.), occurring only in very young children, especially with involvement of the right lung.

Immediately preceding the crisis the condition of the little patient appears especially grave, even worse than it had been previously, so that the improvement that follows seems all the more pronounced. Nevertheless in not a small proportion of the cases improvement does not immediately succeed the crisis. In especially severe cases symptoms of exhaustion may be present for a day or two after this event.

The course of croupous pneumonia in children is noteworthy for its variability. Some cases pursue an abortive course, the infiltration, though marked, being circumscribed and undergoing rapid resolution. Less commonly the morbid process stops at the stage of congestion. Wandering pneumonia is the most dangerous clinical anomaly in childhood. As in adults, so in children, relapses are rare. In the cases of so-called gastric pneumonia, gastro-intestinal symptoms predominate, while the physical signs are not pronounced and appear late, so that the diagnosis may be attended with great difficulty. One of the most common atypical forms of pneumonia is attended with cerebral symptoms, which may be of convulsive, comatose or delirious character. This is usually associated with infiltration of the right lung and appears not more common in association with involvement of the apex than with that of the base. In many cases albumin is present in the urine and often acute otitis media occurs as a complication. The cerebral manifestations may be attributed to the pyrexia, to individual predisposition, to the intensity of the infection and to disease of the middle ear. When meningitis is present as a complication it usually pursues a latent course.

Examination of the blood discloses a variable increase in the number of leukocytes, which bears no apparent relation to the extent of the exudate and but little to the temperature, although it seems to depend in degree upon the intensity of the infection. The number undergoes diminution in association with the crisis, in the sequence of which it becomes normal. The number of erythrocytes is at this time also diminished. Before the crisis the hemoglobin is generally increased, but subsequently its percentage slowly declines.

Pleurisy was present in 51 of the 173 cases, especially with involvement of the lower lobes, in the largest number merely as an epiphenomenon, but in 16 as a distinct complication. Empyema was encountered in seven cases. In addition to seven fatal cases, heart-failure occurred in twenty cases and collapse in five. Albuminuria is less common in children than in adults, occurring in 28 per cent. of the cases, as compared with from 42 to 68 per cent. in adults. Usually it was slight in degree and corresponded with the severity of the attack. Rarely were tube-casts present. One case was complicated by acute hemorrhagic nephritis; and in two others there was nephritis following measles. Herpes was present in thirty-one cases—18 per cent. All of these recovered and the larger number pursued a mild course. In eighteen cases acute otitis media occurred as a complication, pursuing a relatively benign course. There was moderate loss of weight during the attack, which was, however, made good in a short time. The mortality was 4 per cent., as compared with from 10 to 20 per cent. in adults, and with 65 per cent. in cases of broncho-pneumonia. In the seven fatal cases death was due respectively to meningitis (associated with purulent pericarditis and broncho-pneumonia), intensity of the infection (associated with nephritis and enteritis), pericarditis and empyema (associated with enteritis), pulmonary insufficiency (associated with empyema, purulent pericarditis and nephritis in one case, and with empyema, purulent pericarditis, broncho-pneumonia and nephritis in a second case), cardiac insufficiency (associated with empyema, nephritis and broncho-pneumonia) and cerebral thrombosis (associated with anemia and nephritis).

The diagnosis is not based upon any one single symptom or phenomenon, but upon the general impression made by the sum of all of the symptoms. The therapeutic indication in a self-limited disease like croupous pneumonia is to sustain life till recovery takes place. To this end the temperature should be kept within control and heart-failure prevented. High temperature is best reduced under these circumstances by means of the wet pack, especially when restlessness is marked and delirium active. The water used should have a temperature of from 13 to 15 to 18 degrees C.

The investigations of Duerck showed that the lungs of children suffering from the various forms of pneumonia of both primary and secondary origin contain more or less complex mixtures of microörganisms, among which the diplococcus pneumoniæ preponderates in frequency, both alone and in association with other bacteria. In other respects the constituency of this bacterial mixture bears no relation to the primary disease, except that the diphtheria bacilli were found only in cases of pneumonia complicating or following diphtheria. It was not possible to differentiate histologically lobular from lobar pneumonia. The designation broncho-pneumonia is considered permissible only when extension of the disease from the bronchial terminations to the peribronchial tissues can be demonstrated. It was found that the lungs of persons dead of other diseases and not suffering from pneumonia contained bacterial mixtures similar to those found in cases of pneumonia, and in these also the diplococcus pneumoniæ preponderated. Further, bacteria, some pathogenic, were found in the lungs of domestic animals, such as pigs, oxen, horses, calves, not suffering from pneumonia.

From these observations it seems fair to infer that the normal lungs of healthy individuals always contain pathogenic bacteria, whose mere presence is not sufficient to set up disease. In addition there must be some traumatic or other disturbing influence. It was found experimentally that simple injection into the trachea of animals of the bacteria found in pneumonic lungs is not alone sufficient to induce pneumonia. When, however, irritating substances were injected, either previously or simultaneously or subsequently, pneumonia resulted. Injection of the latter alone also proved capable of causing pneumonia, and exposure to cold likewise was followed by the development of pneumonia of lobar, fibrinous and mycotic type. These two forms of pneumonia owe their origin to injury of the pulmonary structure, in consequence of which the microörganisms already present undergo multiplication and acquire pathogenic properties. The harmful influence of cold depends in all probability upon the induction of an acute intense hyperemia of the lungs. The presence of pathogenic bacteria in the normal lungs of healthy persons helps to make clear the occurrence of the so-called mixed or secondary infection of tuberculosis.

ON THE TREATMENT OF TYPHOID FEVER.

BY E. VIKO, M.A., M.D.

PARK CITY, UTAH.

In 1870 Selmi discovered the ptomains, and later Bouchard pointed out the rôle the ptomains play in infectious diseases; knowing the lesions of typhoid fever and its cause many physicians then came to the conclusion that intestinal antiseptics should be employed in this disease. Silver nitrate was employed in 1860 by Joseph Bell of Glasgow, and later by William Pepper of Philadelphia, who treated 100 consecutive cases without a death. As early as 1883, Da Costa employed thymol with good success; ever since thymol has gained in favor. Naphthalin was praised by Rosbach as an abortive in typhoid fever; Kraemer in 1886, Wilcox in 1887, Sehwald in 1889 and Wolff of Philadelphia in 1891 confirmed Rosbach's observations. Mules (*British Medical Journal*, Feb. 27, 1892) reported that many cases of typhoid could be aborted with naphthol. Salol, calomel, beta-naphthol, turpentine, and mineral acids have received their share of praise.

According to my experience, under proper diet and by the use of intestinal antiseptics, the death rate in typhoid fever ought to be almost *nil*. I have treated several thousand cases and have tried thymol, salol, beta-naphthol, calomel, copper arsenite, guaiacol and mineral acids, either combined or separate. My preference is for thymol, salol, beta-naphthol and calomel. Under their administration the attack can be aborted or shortened, or it will run a mild course. Relapses are apt to occur if the medicine is stopped too soon. I order the medicine used for at least two weeks after the fever has abated. The patient is ordered to drink all the water desired. The water is boiled, cooled and aërated; ice is allowed; milk, if it agrees, is ordered; beef tea and soft-boiled eggs, mild stimulation during convalescence. If the stomach is irritable, rectal feeding of milk and beef tea is resorted to when necessary. My prescriptions generally read:

(For an adult.)

℞	Salol	℈ ij	2	60
	Thymol	℈ ij	2	60
	Tablets cupri arsenitis (āā gr. .01) No. xx			
	Papoid	℈ ij	2	60
	Guaiacol carbonatis	ʒ ss	2	00
	Pulv. saponis	gr. v		33
	M. Ft. caps. No. xx			

Sig.—One every four hours with milk.

(For children.)

℞	Beta-naphthol, dissolved in heated oil	gr. xxiv	1	56
	Ol. amygdal. dulcis, dis. in heated oil	℥ ss	16	00
	Ol. cassiæ	m. j		06
	Pulv. acaciæ	q.s.		
	Glycerini	℥ ss	16	00
	Aq., q.s ad	℥ iij	96	00
	M. Ft. emulsio.			

Sig.—One teaspoonful every four hours with milk for 3-year-old child.

The bowels are moved once or twice a day with calomel and soda. At this place, I desire to express my opinion as regards acetanilid. Most authorities condemn it; in large doses it will certainly do harm. In small doses (4 grs. every three or four hours) I have found it very beneficial; it keeps the temperature inside safe limits and lessens tissue oxidation. It produces sweat, which is certainly desirable. The pulse becomes slower and stronger (action analogous to digitalis). My prescription reads:

℞	Salol, acetanilid	āā ʒ j
	M. Ft. pulv. No. xv.	

Sig.—One every three or four hours when fever goes above 102 degrees F.

Under the above detailed treatment sordes on the tongue never appear, and seldom delirium; hemorrhage from the bowels is rare; death rate is almost *nil*.

A word as to the Woodbridge method. On reading his article in the JOURNAL for July 10, 1897, one is left with the impression that Woodbridge has made a new discovery. His treatment is not new (see short historic sketch at the beginning of this article). The only new and novel thing about it is a variety of tablets and capsules. As to novelty they are certainly admirable; as to practicability they are a nuisance. The drugs used are all good and I do not doubt but that he will have good success with them, but the doses are too small and the intervals between doses are too short, thereby unnecessarily disturbing the patient too often; the purging is also excessive. Larger doses, longer intervals between doses and less purging will produce just as good results if not better. The sentence: "The declaration that typhoid is a curable malady has been for years and is yet nearly always greeted with such 'acrimonious and vituperative dissent,'" etc., is unwarranted, as the writings on intestinal antisepsis are quite extensive and date back to 1870 (see authorities mentioned and also Hare's "System of Practical Therapeutics," 1892).

Permit me to report a curious instance with reference to the cause of an outbreak of typhoid last fall in four families who live outside of town near the mines at a place called the Alliance tunnel. They receive their water supply from a small creek. The water is conducted first through two barrels as a reservoir and thence to their houses. Eleven became sick with typhoid; the youngest was 11 months old, the oldest about 35 years; in some the temperature was normal at from eleven to fifteen days, in others about twenty-one days; in one in thirty-six days and in another about forty days, counting the relapses. All got well. The average duration of the disease was fourteen or fifteen days. Undoubtedly several more cases would have occurred in those families had they not been instructed to boil their drinking water. Later the barrels used as reservoirs were cleaned out and three more or less decomposed squirrels were found in the barrels.

Some two or three years ago this town used to be a regular hotbed for typhoid fever. The cause was in the water supply. The fever would be most severe in December and January; at that time the usual water supply was insufficient and water from a stream polluted with human excrement was turned into the city reservoirs.

THE USE AND THE ABUSE OF THE BICYCLE.

Read before the Central Wisconsin Medical Society, at Evansville, Wis., June 29, 1897.

BY JAMES MILLS, M.S., M.D.

JANESVILLE, WIS.

The world is on wheels; doctors and ministers, lawyers and teachers, husbands and wives, kings and queens, old and young, rich and poor, are all equal in cycling; and all must pedal, sweat and breathe dust alike. In this they share the same joys and sorrows. Cars and steamboats are wholesome affairs, so far as equalizing our outward conditions is concerned; but your true leveler in locomotion is the bicycle.

In this " age of inventions," what the telegraph and the telephone do for thought and voice, the bicycle does for the body. It is a machine with the power of impulsion induced by the muscular motion of the rider's limbs; it is a horse and buggy combined; costs less than either and fattens on air. It enables the doctor to outride microbes, and catch ozone on the wing. It puts him in prime condition for visiting his patients, and is an amazing economizer of his time and energy. It suggests to him the importance of caution, courage, courtesy and self-reliance; and particularly of " looking before leaping." Like the moth that circles about the flame, he will find the danger of " scorching"; and possibly like it, take warning from the sad mishaps of others who often outride him.

It is for the general public interest, that legitimate and orderly cycling should be encouraged. The use of the bicycle for traveling, especially in the country, has in it the germ of the solution of the improvement of public highways. When wheelmen have become sufficiently banded together to compel the maintenance of well-paved streets and good roads and the safe use thereof by them, there will be a heavy falling off in the tribute paid by the people to elevated-track magnates and traction barons, who now control our street and railway conveyances, and tax the people for the proud privilege of getting to and from their daily labors.

Beyond all these, there is the certainty of a higher physical standard for the race in the universal employment of a vehicle which insures to its users fresh air and healthful bodily exercise. I believe that the bicycle, properly used, is of very great value to a large number of people who would not otherwise indulge in sufficient outdoor activity.

The majority of accidents to cyclers in the cities are the results of inexperience in riding and the carelessness of the drivers of horses. In Germany and some other European countries, this fact is recognized; and before a novice is allowed to go out upon the public highways, he or she is required to give an exhibition of proficiency before duly appointed examiners. We venture to assert that this would obviate many of the present dangers which are universally admitted to need attention, and would thereby appreciably reduce the number of street accidents.

The subject of bicycling for women is beginning to attract the notice of medical writers. Dr. Robert L. Dickinson of Brooklyn, N. Y., is among the foremost who have given the subject attention. Some French, English, German and American gynecologists have given their opinions upon the subject, and the greater number of them agree that, as a rule, where this exercise is not carried to excess, it is a beneficial one.

In it we seem to have found, at last, a form of an open air muscular work, which induces women to spend many hours away from close rooms and indoor tasks. It exercises and strengthens a large number of muscles of the body, far more than is generally supposed. Ask the beginner or the expert, how much bodily balance is required. Ask the woman who sits upright, holding tightly to the handle bars as she works up a grade, how much arm-and-shoulder pull there is in it.

Since bicycling is one of the few popular physical exercises that attract women, it will, under properly prescribed conditions undoubtedly show itself capable of large results as an agent in curing pelvic disorders. There is no problem that troubles the physician more than the prescription for proper physical exercise by women in view of her disabilities and the disadvantages under which she has suffered in attempts to obtain pleasurable and beneficial muscular action. It seems hardly too much to say that the promises from the bicycle are far-reaching. Through it and the habits it will engender, we look for better and freer dress; for rounder limbs, fuller lung cavities, steadier nerves, and better developed muscles.

There are four demands before which the costume of the wheelwoman must pass in review: health, fitness, fashion and artistic beauty.

The third of these is ever at odds with the others. As for art in personal adornment, it can not be said to exist among people who tolerate a combination of sweaters, bloomers and leggings, or the deformed wheelwoman of alleged fashion journals. Yet the principle at the foundation of the dress question seems exceedingly simple. For play of the muscles, freedom is the first requisite, whether in cycling or scrubbing; and we must therefore instruct our patients to make certain modifications of their dress as necessary.

One has but to glance at ten riders of the hampered sex, to see nine who, ignorant of some of the rules of good riding, misapply force, waste effort, and run a certain risk of harm to themselves. The trouble is due chiefly to the lack of training, since the pupil in bicycling is turned adrift on the road as soon as she can balance a wheel or can mount and dismount one. Instruction should be insisted upon to obviate bad habits of riding; and unmerited criticism will thus be avoided.

It would be superfluous before an audience of physicians to do more than to name the ordinary precautions necessary for women who take up wheeling.

We lay stress on carefully increasing the length of the ride, and on strict attention to the difficulties thus experienced; on heeding the warning given by palpitation of the heart and by labored breathing; on signs of strain of the right heart, which is robust only in laborers and athletes; on frequent rests; on giving heed to chilling and over fatigue; on light food during exercise; on relaxation of the muscles after riding; and on entire abstinence from such riding during the menstrual period.

I have the report of the wife of a physician, who, after riding her wheel for half an hour against a hard wind, had sudden cardiac dilatation, which gave rise to very serious symptoms, and which it required eight months to reduce.

No physical exercise has proved to be more beneficial in many insane hospitals than the riding of the wheel. It is attractive, novel and interesting to the patients, and brings excellent curative results.

Bicycle riding has certain advantages over the present style of horseback riding. The fashionable contorted seat on a saddle horse does not develop the body symmetrically, and the awkwardness, due to the fact that the transverse diameter of the pelvis and the transverse diameter of the upper trunk do not correspond, means strain, to say nothing of the useless effort that a trotting gait entails.

When women get into the habit of riding on horseback, part of the time with the stirrup on the right side, and part of the time with the stirrup on the left, one objection to the spinal rotation and the unsymmetrical development will be overcome; and it is to be presumed that eventually all women will ride astride, as their great-grandmothers did before the days of Elizabeth. Expense precludes this form of exercise for most women. Cheapness, safety, accessibility, and the small amount of preparation required, are all on the side of the wheel, and hold good even to a greater degree for women than for men.

The question is often asked, how is it that we advise women to ride a wheel, while a strong protest has been entered against her running the sewing machine, on account of the harm it may do to her pelvic organs. It seems to me that the conditions under which the two forms of leg exercise are taken, are radically different. A woman at the sewing machine must focus her eyes accurately on the point at which the needle is at work, and must drive the material along in even lines under the rapidly moving needle and within the margin of one-sixteenth of an inch. Such a position to a corseted woman brings a strong pressure on the the pelvic contents and prevents free circulation.

A word of warning is needed as to the undue pressure that the bicycle seat is liable to make upon the parts of the body in contact with it.

The seat of the bicycle for men seems to have been modeled after the saddle that was found suitable in riding horseback.

Women have generally found great difficulty in having the seat so adjusted as to be comfortable to them.

To relieve them in this respect, several alterations become necessary. In the first place, a woman's pelvis is broader than a man's; and the tuberosities of the ischia are farther apart in woman than in man; consequently, the width of the rear portion of the seat needs to be greater. Secondly, the anterior projection of the seat must be tilted downward. This, however, requires the most delicate adjustment; for if the seat is tilted too far, its slope will cause the rider to slide forward, so as to rest almost entirely upon its anterior projection, and so defeat the object of the tilting.

There are two possible objections to bicycling by women. The one, over exertion, should be and is easily controlled; the other may be entirely eliminated by the use of the proper seat. Bicycle riding can do no possible harm to a healthy woman, any more than it can to a man, unless it is abused. And for neurasthenics it is an excellent remedy, probably the most valuable we have.

The principal points connected with the proper construction of the machine itself are those relative to a proper fitting seat and an arrangement of its parts enabling the rider to assume a reasonably erect position, so that the weight of the body is in part upon the pelvic bone, and the rest of it is borne by the feet upon the pedals and the hands upon the bars.

Physicians ought to have personal knowledge of this exercise. It is our duty to so advise wheel-women that they may be carefully trained by competent instructors as to the right methods of pedaling, the correct position of the body, and the height of the seat.

It is plain that the wheel is destined to make a place for itself in the world, not only as a luxury and source of pleasure, but as a positive necessity for health and physical development to hundreds of thousands.

FRACTURES OF THE SKULL AND INJURIES TO THE BRAIN.

Read before the Milwaukee Medical Society, May 25, 1897.

BY F. SHIMONEK, M.D.

SURGEON TO THE JOHNSTONE EMERGENCY HOSPITAL.
MILWAUKEE, WIS.

Case 1.—B. F., German, age 35 years,, book agent; was brought into the Emergency May 1, 1897, about midnight: unconscious, right motor hemiplegia, respiration labored and irregular and of Cheyne-Stokes character, hemorrhage from right ear. Pulse 70, full and stong, indicating cerebral compression; temperature, 97 degrees; by next morning it had arisen to 100.2 degrees and pulse to 98; respirations, 26.

History: About 10 P.M., while intoxicated, fell down stairs and was not found until about midnight. I saw him the following morning in the above-stated condition.

Examination: The scalp was very greatly swollen, so much so that it was impossible to make out the condition of the skull underlying this tumefaction. There were no marks of injury upon the scalp. An oblong edema extended from a little distance behind the bregma on the right side of the head downward and backward to the apex of the mastoid process. May 2, pulse, 84; temperature, 99.2; respirations, 20; temperature rose to 101 degrees. Ice was applied immediately and this application kept up until May 3, when examination revealed a little motion in the right arm and leg and not quite such profound unconsciousness. The edema having somewhat subsided we were able to feel a short ridge, which we decided to be a fracture.

It is a known fact that a simple exudate in the scalp, or rather in the pericranium, is frequently mistaken for a fracture; but it is quite easy to differentiate an exudate from a ridge of a fractured bone by simply taking into consideration the fact that an exudate being a displaceable material, can by pressure applied firmly and steadily for a few seconds be indented and made to yield before the finger, while a ridge due to a fracture will not yield to pressure and is more likely to make a dent in the finger. It will be noticed that the injury on the head, the bleeding from the right ear and the paralysis were on the right side; according to cerebral localization it follows, therefore, that the lesion causing the paralysis was an injury, through *contré coup*, of the opposite motor center, and that part of it which controls the leg and arm.

Operation: Assisted by Drs. Chandler and Hanson, May 3, 12:45 P.M., a large U-shaped incision was made over the right parietal bone, just posterior and inferior to the eminence, surrounding the supposed fracture. A piece of loose bone, about an inch square, directed vertically inward, was found. It was necessary to remove a button of bone before this could be removed. The dura mater was uninjured. After extraction of the bone the compressed brain very slowly filled the space, but was perfectly pulseless. From this piece another fissure extended in the direction of the sagittal suture, thence downward and outward, describing almost a perfect circle, and having a diameter of two and one-half inches. This area was also loose so far as bony connections were concerned, but was still attached to the pericranium; one edge of it was so firmly fixed beneath the skull that all our efforts to bring it into contact with the skull and retain it were without avail, so its removal was deemed the lesser evil. Still another fissure, running downward in the direction of the petrous portion was found, and this explained the hemorrhage from the ear.

The night following the operation some signs of improvement appeared, such as continuous talking and diminishing paralysis. Temperature, 99.2 to 101, axilla; pulse, 92 to 99.

May 5, 9:30 A.M. The wound was dressed and union found perfect, with no cerebral pulsation. The patient asked for water, complaining of headache. Temperature. 98.6 to 100, axilla; pulse, 78 to 88; respirations, 21. He was perfectly conscious; talked rationally about his affairs and relatives; moved arm and leg quite easily.

The unconsciousness was due to the depressed fragment of bone; the motor paralysis to an injury of the opposite motor center, the pulselessness to an hemorrhagic exudate, probably into the lateral ventricles. The improvement after the operation simply followed the relief of pressure.

May 8. Temperature, 99.4 to 98.4; pulse, 80 to 78; 3:20 P.M., he became again unconscious and could not be aroused.

May 9, 6:30, regained consciousness, complained of headache and again became profoundly comatose with complete motor paralysis of right side.

May 10. Temperature, 98 to 100, axilla; pulse, 68 to 82, full; respirations, 22; completely unconscious all day.

May 11. Temperature, 98.4 degrees; pulse, 76; still profound coma. At 5:45 it was decided to open the skull upon the opposite side, *i. e.*, over the middle meningeal artery, because it was suspected that a fresh hemorrhage was causing the unconsciousness and paralysis. With the assistance of Drs. Chandler and Hanson I trephined on the left side. A small clot with quite a quantity of venous blood escaped. I believe that an accidental injury to a vein caused the venous hemorrhage; the brain upon that side, also, was perfectly pulseless, demonstrating the fact that there was intracerebral pressure. The patient was so profoundly comatose that the operation was done without an anesthetic and he did not manifest any sign of sensation. Respiration was decidedly Cheyne-Stokes.

May 12. Temperature, 98 to 100; pulse, 78 to 124; respiration stertorous; complete unconsciousness.

May 13. Temperature, 99.4 to 98.4 degrees; pulse, 102 to 108. The patient was still unconscious and right motor paralysis still existed. The wound was dressed and found aseptic.

May 13, 10:20 A.M. He became conscious and asked for lemonade The paralysis was somewhat improved.

May 14. Temperature, 98.8 degrees; pulse 101 to 77; respiration, normal. Patient was perfectly conscious and paralysis vanishing and absolute asepsis continued. The patient returned home May 22, weak but perfectly well and after twenty days of pulselessness his brain is again normally pulsating.

Case 2.—S. D., injured by a falling scantling which struck him on the temporal region. He died on the way to the hospital. There were no external marks, but brain and blood were exuding from the meatus auditorius externus in considerable quantities.

Case 3.—M. K., injured by falling from a building. He struck on the right temple and when picked up was completely unconscious and had a left spastic paralysis, with an occasional tremor of the paralyzed side. It is not known whether he was immediately comatose as he was not missed until several hours had elapsed. Two buttons of bone were removed from over the middle meningeal artery of the right side. No hemorrhage was found but a large quantity of very clear serum escaped. No benefit followed the trephining and the patient died the next morning. I believe that the lesion in this case was a cerebral laceration extending into the lateral ventricles and permitting the escape of the cerebro-spinal fluid through the Sylvian fissure and out through the trephining opening.

ON A CASE OF THE PARTIAL REMOVAL OF THE SPLEEN.

BY HORACE M. DEEBLE, M.D.
Late Acting Assistant Surgeon United States Army; Member American Medical Association; Member and Treasurer of the Medical Association of the District of Columbia; Member of the Medical Society of the District of Columbia, etc.
WASHINGTON, D. C.

One evening in May, 1889, about 7 o'clock, and while stationed at Fort Yates, North Dakota, I was summoned to the Indian hospital, three miles south of the post, to examine a 12-year-old Indian boy that had met with an accident. A short time before, the patient had been leading a pony to which was attached the usual lariat and picket-pin. From some cause or another the animal became frightened, and in its alarm violently jerked the lariat rope, which had the effect of sending the iron pin at its free end flying through the air and this struck the boy in the left side between the fifth and sixth ribs, inflicting an incised wound some fifteen centimeters in length. Through this opening protruded a tumor, which was dark in color, and measured in diameter about seven centimeters. Upon examining this it was seen that it could be nothing more nor less than the boy's spleen. The organ was, moreover, in the most unsatisfactory condition, owing to the fact that the parents of the child had made numerous and violents attempts to squeeze the mass back into their son's body through the lips of the wound. This undue handling had gotten the organ into the most filthy condition imaginable and, of course, in the very worst state for the interference of the surgeon. To make matters still more serious, I had come to the hospital armed only with my pocket-case and no antiseptics. To replace this bruised and lacerated spleen within the abdomen of the patient would, I was certain, prove to be a fatal procedure, as profound suppuration together with infection of neighboring structures would quickly follow beyond all peradventure of a doubt.

Under these circumstances there was but one thing left for me to do, which was to remove the organ. This was promptly done, having first encircled the mass at its base with a ligature. Then cleansing the stump as thoroughly as possible with hot water, I returned the former into the abdominal cavity and closed the external wound. There was a lady physician in charge of this hospital and to her I turned over the case, hearing nothing further from it until about 6 P.M. on the third day after the operation, when I was sent for in great haste. Carrying with me the proper antiseptics and dressings I was soon at the patient's bedside, where the preliminary examination revealed the fact that the temperature had arisen to 104.4 degrees; the patient was, moreover, extremely restless and the margins of the wound were greatly swollen and bulged outward. Upon removing the stitches there immediately escaped 60 c.c. of very offensive pus, and in this floated the ligature, which had come away. Washing out the cavity with a solution of hydrogen peroxid (1 part to 4 of water) until all foaming had ceased, I next inserted a rubber drainage tube and dressed the wound with bichlorid of mercury gauze, placing the whole in as favorable a condition as possible. Good effects immediately followed, for the child's temperature at the conclusion of the toilet of the wound fell from 104.4 to 100.4 F. At my first visit I had instructed the attendants to allow their patient only liquid food, but these instructions had not been carried out; for the parents had succeeded in smuggling in a quantity of dried peaches, which he had consumed; fortunately, however, without any deleterious effects. From this time on, the patient made an uninterrupted recovery, and after the second dressing no pus accumulated in the wound.

Prior to his injury this young Indian was but a light eater, while in temperament he was mild and docile. A marked change in both these respects took place, however, after I had relieved him of at least three-fourths of his spleen. Almost immediately his appetite became ravenous and the amount of food it took to appease it was quite incredible. *Pari passu*, with the development of this enormous appetite the boy's temperament underwent a complete change, and instead of being gentle and good-natured, he gradually, though rapidly, became exceedingly irritable and querulous. Two years subsequently, when the opportunity was again afforded to examine this patient, I found that no change had taken place either in his appetite or nature. After his recovery, I regret to say that I made no examination of the blood of this boy, although I was enabled to observe that he was lacking neither in the matter of growth nor development. He was likewise well nourished.

There have been very few traumatic injuries of the spleen reported, and one authority consulted by me, makes the statement, that out of twenty-nine cases of gunshot wound of this organ, there were but two recoveries. The present case confirms much that has been written in reference to the effect upon the appetite, following extirpation of the spleen, while upon the other hand little has been said in literature touching the effect the removal of this organ has upon the disposition of the patient.

In Flint's "Text-book of Human Physiology," he sums up with more or less thoroughness the effect which eradication has upon most dogs and other animals below man. This eminent authority makes full reference to the changes which take place in the appetite, such as marked increase in the voracity as well as depravity, the subject sometimes not being averse to the eating of feces and flesh of its own kind. He also quite fully refers to the changes in the disposition of the animal.

Nevertheless, there is a great deal yet to be known in regard to the physiology of this peculiar ductless gland, and upon this occasion I can only say that I feel a deep sense of regret that I did not bring this boy under a closer examination the entire time it was within my power to do so. The opportunity may at least have afforded confirmation of doubtful points which now stand in need of additional material to clear them up.

602 M Street N.W.

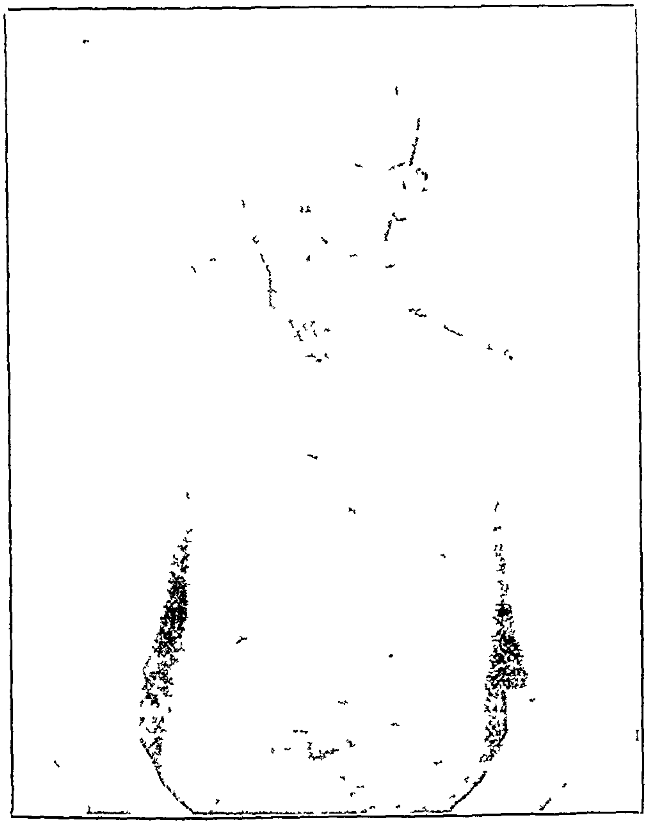
AN UNUSUAL CASE OF VARICOSE VEINS.

BY B. J. WETHERBY, M.D.
WILKESBARRE, PA

I wish to report what has been to me an unusual and interesting case of varicose veins. The patient, Carl Mitchell of Arlington, Kansas, has been under my observation more or less constantly, on account of an intimate friendship, and near residence, during the past ten years, until I removed from the State, six months ago. He is now about twenty-six years of age, married, and by occupation a farmer. Until three years ago he was in perfect health, with the exception of a very obstinate acne vulgaris of the face, shoulders and breast, which still persists, although in a much modified form. His parents are both living and in good health. He has two sisters, living and healthy. He has never had gonorrhea or syphilis. Three years ago he was rather suddenly seized with pain in Scarpa's triangle, over the femoral vein of the left side, which was followed by the development of a sausage-shaped tumor about six inches long, in the same region. There was no history of traumatism, exposure or undue fatigue. The pain was aggravated when he attempted to walk or assumed the upright position. There was fever, anorexia, furred tongue, constipation and all the symptoms of acute inflammation. The leg on the affected side became edematous, and albumin occurred in the urine. A diagnosis of phlebitis of the femoral vein was made, and the patient confined to bed. The abdomen became very tender and the constipation more obstinate. In about ten days a tumor developed over the femoral vein in the triangle on the right side, followed by edema of the right foot and leg. The acute symptoms lasted about five weeks. Convalescence was very slow, extending over a period of several months.

Following the subsidence of the acute symptoms the superficial epigastric and superficial circumflex iliac veins on both sides began to enlarge, which they continued to do until all the superficial veins of the abdomen were of sizes varying from that of the little finger to that of a goose quill. They can be traced with the eye to the level of the fourth rib. I succeeded in getting a rather poor photograph, which is here presented.

My theory was that a phlebitis began in the left femoral vein, traveled up the external and common iliac of the left side to the bifurcation of the inferior vena cava, then traveled down the right common and external iliac veins to the right femoral. The inflammation almost or entirely obliterated the veins involved causing almost if not the entire return circulation from the lower limbs to be carried on by the superficial epigastrics and superficial circumflex iliacs through their anastomoses with the mammary and intercostals. I presented the case before the Kansas City Academy of Medicine and nearly all the members agreed with this theory. Dr. Cordier and Dr. Binnie of Kansas City examined the case in private and endorsed my views. No one with whom I have talked regarding the case has ever seen a similar one, hence my desire to report it.



At present he is feeling fairly well and doing work on his farm. Both legs are somewhat edematous, and at times his abdomen contains considerable fluid.

An occasional hydragogue cathartic and a constant use of laxatives keeps the edema from giving much trouble. He has an ulcer on each leg which is alternately healing and discharging. There are no varicose veins in the legs. I have advised elastic stockings extending to the groins, to be worn on both legs, and a change to a lighter occupation.

SURGERY ONE HUNDRED YEARS AGO.

AN HISTORICAL STUDY

BY DR. GEORGE FISCHER.

DEDICATED TO THE GERMAN SURGICAL ASSOCIATION.

TRANSLATED FOR THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION BY CARL H. VON KLEIN, A.M., M.D.

(Continued from page 237.)

X.—ENGLISH SURGERY. JOHN HUNTER.

Bacon von Verulam; Maxims of English Surgery; The English: Cheselden, Sharp, Bromfield, White, Gooch, Alanson, Warner, Wilmer, Hill; Pott; 4 Scotch families: Alex. Munro with his sons Donald and Alexander; Benjamin, John and Charles Bell; Allan and John Burns; William and John Hunter. Surgeons in the remaining foreign countries.

A nation which was in possession of the commerce of the world, and ruled the sea, hardened by an inhospitable climate and given to the dangers of the open sea; a people with strong practical sense, mightily stimulated to the study of nature by continuous traveling, rich in material wealth, having built in their own home a number of most excellent hospitals, whose physicians had practiced in the most remote regions of the earth, and had there learned the diversity of prevailing diseases—In what spirit must this people pursue its sciences? Those very qualities make it probable, that the English, instead of clinging to speculations and hypotheses in their researches, would much rather hold to simple observation and experience.

In its lord chancellor and keeper of the great seal, *Francis Bacon*, Lord Verulam (born 1560), England produced a great genius whose philosophy, through the application of the inductive method, brought about a complete revolution in all experimental sciences, and especially in medicine. It was the method of arriving at general principles from isolated experiences, in contrast to the deductive method of descending from general principles to particular cases. One should pass cautiously and slowly from the particular observations, accurately weighing the circumstances and modifications, to the general propositions; for only in this way and with much difficulty will progress be made. Experience alone will be of little use, if one does not know how to deduce causes from it, and it is just as harmful to portray nature according to preconceived opinions and favorite theories. Bacon demanded an accurate history of a case which must be neither so verbose as to include the most commonplace trifles, nor so meager as to relate only the miraculous. Good observers might find in the most ordinary things much that was noteworthy. Departures from a normal structure of parts and also comparative anatomy, had been too much neglected, while advancement in medicine had been especially retarded by a too great veneration for antiquity. It was foolish to perpetually quote the authorities; man must study nature, for as a rule there was not much wisdom in books, since they continually contradicted each other. These empirical views of Bacon which opposed all useless substitutes, were carried still farther by Locke and Sydenham. The latter laid clear before the eyes of his contemporaries, the great mischief of the mania for hypotheses, and led them back to the observation of nature. After Bacon's idea, the architect Wren founded in 1657 the Royal Society, whose object was the study of all nature. In the beginning of the eighteenth century, Locke (1704) and Newton (1724) died and England lacked for half a century, until John Hunter came, great thinkers who advanced comprehensive views of natural phenomena. But the British still valued sensual perception as the only source of knowledge. Proud of their healthy human understanding and practical insight, the British nation was an enemy to all general hypotheses, declaring openly that their business was with facts, and despising every theory from which a direct use could not be expected. The discovery of a new salt or the invention of a new machine, meant to them far more than the deepest speculation. The study of nature was everywhere insisted on, even though it sometimes went astray. This explains the voluminousness with which every natural product was described and catalogued. For instance, the frog hopping about in every conceivable aspect, occupied a whole volume; and also the immoderate partiality for the miraculous filled their medical literature with curiosities. Indeed, the practitioners complained that in all the investigations and classifications of worms, they forgot to study the symptoms of worms in the human body and the means of eradicating them, and never thought of the great profit which the science won from the enthusiastic study of nature. For the first time Newton, discarding all hypotheses, taught students to base conclusions on observation, and with mathematical exactness, to build one proposition upon another, assuming nothing without proof. The English nation assented to this, for they were more empirical than any other nation in Europe.

A reaction in English surgery was not lacking; here also empiricism carried the banner. "A grain of experience to a practical surgeon is worth a pound of reasoning;" with this maxim Kirkland criticised the views of his countrymen. (In Germany A. G. Richter and Schmucker adopted these winged words, except that the latter changed the grain to a drachm.) The love of the natural and unartificial, a national characteristic of the English, gave to surgery a different direction to what it took in France. The animated and fervid power of the French, which, with real zeal multiplied useless instruments and increased superfluous methods of operation, was observed by the Englishman quietly and thoughtfully, while he followed nature and sought to make his surgery as simple as possible. They operated with the greatest complacency. They took pride in performing almost all operations with the surgical knife alone, and simplified many instruments; indeed, as simplicity in instruments is almost always the measure of this perfection, and nothing shows better the poverty of our art than the multiplicity of instruments and bandages. They cast a great many of the latter into the lumber-room and looked upon bandaging as a very subordinate branch of surgery. The surgeons industriously cultivated anatomy, in spite of the fact that this study was made difficult by prejudice and other hindrances, and gave to their surgery a new impetus such as the French had given to theirs. Accordingly, their best surgeons were at the same time the best anatomists (Cheselden, the Hunters, Monro and Bell). They did not stand second to the grand nation in operative skill, and found rich opportunity for training in the wars and in the many hospitals. It was not long before English surgery excited public attention, in spite of the brilliancy of their French rivals. It was seen that in the English hospitals the mortality after operations was much less than in the French, and it was realized that the better hospital equipment contributed to this result, as did also the great simplicity on the part of the surgeons, who also had more thorough medical knowledge than their neighbors and a greater appreciation of after-treatment and diet. The English followed a strictly conservative policy. They tested the new, but with discretion. Indeed, it was difficult for an innovation to find acceptance, but when proven successful it was introduced and strenuously maintained. They had a high reverence for what had been once tested, and for the traditional; their retention of tried principles and faithfulness in their application, were the chief qualities of English surgeons. Their great harmony in respect to the most important questions of practice, soon gave to their surgery a definite national aspect. It was a great merit in certain eminent men as Percival Pott and Benjamin Bell, that they although themselves highly esteemed as operators of the first rank, by no means placed the chief value of surgery in operating, and sought to check the undue zeal of the young men of that day for operating and to impress upon them the value of pathologic surgery. For with a little anatomic knowledge, coolness and a firm hand, any one could perform the most difficult operations with tolerable success, but for the proper diagnosis and treatment of a wound, knowledge was demanded which but few surgeons possessed. Of no less importance was the growing union of the study of medicine and surgery, for which Kirkland, among others, zealously contended (1783).

Although, not until the year 1800, did the state separate the college of surgeons from the guild of the barbers, yet surgery in Great Britain was considered one of the free professions, and, chiefly through John Hunter, had as a science been elevated to the level of medicine. In contrast to other nations of Europe, where it was despised, surgery was valued and honored. Frequently youths of the best families devoted themselves to its study; men of high rank attended surgical and anatomic lectures and had their allotted place in the ampitheaters. In general, the whole nation showed more sense and confidence in surgery than was shown elsewhere. This has continued to our own day. Even yet the success of herniotomy is greater in England than in other countries, because the sufferer notifies the physician earlier, and the operation is therefore earlier undertaken, a circumstance which also favors the prognosis of stone in the bladder, as the patients seek medical aid earlier than is the case in our own country. The English showed a high degree of enthusiasm for their profession, and in spite of the large number of skilled surgeons, four to six of whom frequently served in the same hospital in London, they were very friendly with each other and exchanged their opinions in mutual consultations. free from jealousy and prejudice. A great impetus was also given by the various societies. London had a college of surgeons, of physicians, the Royal Society, the Society of Physicians and several private societies; Edinburgh and Dublin likewise had their colleges of surgeons. These published their journals. The "Edinburgh Medical Essays" (1732) and the "Medical Observations and Enquiries," were followed by the "Medical Transactions" published by the College of Physicians in London, (1768), and the "Memoirs of the Medical Society of London" (1787), which was published by physicians, surgeons and apothecaries. How high a standard was maintained by the latter society, which consisted of thirty members, is shown by the fact that no one who possessed a secret remedy was admitted to its membership. In the year 1805, the Medico-Surgical Society was founded; its published proceedings ("Med. Chir. Transactions") have become of the utmost importance. The surgeons and apothecaries were really the family physicians, while the physicians were only called in difficult cases. In 1797 it was suggested that all medical persons be given the common name of doctor of health, analogous to the French officiers de santé, but in vain. The surgeons remained in the guilds until very recently; a sharp distinction was made between surgeons, physicians and general practitioners. The latter were the so-called apothecaries who practiced medicine, surgery and obstetrics, and prepared in their own houses the medicines for their patients.

The excellent hospitals laid the foundation, in the beginning of the 18th century, for the great medical and surgical schools. *Cheselden*, of St. Thomas Hospital in London, body-surgeon to the queen of England, introduced this period. He wrote little but accomplished all the more. We have him to thank for ingenious descriptions of the eye, which he first undertook in 1718, but described very briefly and vaguely in his anatomy, which later, Blumenbach had translated. Then he introduced a method of lateral incision for lithotomy (1730), which gained him the greatest applause. He had at first many failures in lithotomy, through the frequent injury of the rectum, which he honestly acknowledged, until his method, by which Morand saw him complete an operation in fifty-four seconds, gave him better results. From him we get the first description of neuroma. His best pupil was *Sharp*, of Guy's Hospital, who as a young man wrote a work on operation (1740), characteristic for clearness, brevity and simplicity, which England lacked at that time. An enemy to the mania for authorities, and the customary routine, endowed with great mechanical talent, he improved many operations and instruments, but carried it so far, that he looked with contempt on all directions for the adjustment of bandages. Whatever good French surgery accomplished, he brought to England, after his studies in Paris, in his "Critical Inquiry" (1750). *Bromfield*, at St. Luke's Hospital, was the champion of the isolated ligature of the arteries, for the drawing out of which he invented his hook. His successful exarticulations of the humerus are well known, as well as his successful extractions of foreign bodies from the knee-joint, his zeal against the abuse of amputation and bleeding, and against the debilitating treatment for erysipelas ("Chir. observ. and cases," 1773). *Charles White* of Manchester, as the father of joint resection became immortal. We owe to him the method of setting the dislocated upper arm by extension upward, and the recommendation of the amputation of the lower part of the femur, above the condyles ("Cases in surgery," 1770). *Benjamin Gooch*, in Shottisham, a bold operater, wrote much on wounds and stones, first observed a caput obstipum through shortening of the platysma myoides (1759), and invented a bandage for concrement of the knee-joint that the operation might be avoided ("Chir. works," 3 vols. 1792). *Alanson* in Liverpool, introduced a new flap in amputations (1779), and recommended thereby prima intentio. *Warner*, the successor of Sharp in Guy's Hospital, described fine operations in empyema, and specialized in diseases of the eyes, and of the testicles. His "Cases in Surgery" (1754) as well as those of *Wilmer* (1779) and Hill (1772) are rich in peculiar observations.

Percival Pott (1713–1788) was more eminent than these contemporaries. He had pursued his studies in Bartholomew's Hospital in London, had become assistant there and, soon afterward (1749), first surgeon. He held this position for thirty-eight years, then retired, and died a year later. Pott was considered the best practitical surgeon, the best teacher, the best writer, and the best operator of his time in London. However, had a few of his country-men inaugurated with him a new epoch in English surgery, the history of this verdict would have been changed. Pott may have surpassed his colleagues in scientific accomplishment and rich experience so far as actually to have commanded the most varied departments of practical surgery; the great honor of bringing about many reforms in English surgery remains to him; he did not make a new epoch, as did John Hunter. That time alone could alter that judgment, was due to the fact, that Potts's improvements were recognized by everyone, while John Hunter's higher intellectual attainment and the influence of his pioneer work were only fully appreciated by posterity.

A certain clumsiness and crudeness clung to many surgeons until within the eighteenth century. They gloried in a kind of cruelty and overlooked the feelings of the patients so far that the ordinary man must believe that the patient was not given proper care unless he was heard to groan. They did not understand the first principles of surgery; the after-treatment was tedious and painful, the bandage a heap of irritants, the instruments endless and awkward, the red-hot iron an attribute of every hospital visit. Pott opposed all this and showed that all we need to do is to observe the working of natural forces in the process of healing, not retard their operation but help them. Sometimes nature overcomes the worst art. Pott endeavored to make surgery less painful and operations simpler, to almost completely abolish the hot-iron, to use corrosives more sparingly, and especially to use fewer external remedies and fewer but more serviceable instruments. An instrument could not be too simple nor too sharp for him, and a bandage could never be light and soft enough. Pott considered the art of avoiding an operation and curing an injury without it, higher than that of operating cleverly, since it often required more skill and judgment to preserve a member than to operate on it. He noticed that his hearers, more than half of whom were apothecaries who when they came to London had seen little or nothing of surgery, as well as the many foreigners in his hospital, turned their attention almost wholly to operations. They judged the surgeon only by his quickness, and watch in hand timed him. Then he reminded them that while a certain celerity pertained to a good operation, the safety of it always stood first, but while he urged them to a diligent study of pathologic surgery, and influenced them against operations, he took care to train up good operators; this, however, was not to be the main object. For a long time his pupils were to see and think for themselves, since neither through the brief instruction of a few months' course in the hospital, nor through the study of books alone, could one acquire judgment and skill. The rules of writers are always but the outlines of a drawing which the surgeon has to fill in and complete. Pott insisted strenuously upon accurate sections and anatomic studies as the basis of surgery. A wide experience confirmed him in an aversion to all useless theories. He knew the old writers and sometimes quoted them, always quoting the Greeks in the Latin language (for at that time no one thought of reading Hippocrates and Galen in the original); but there was no trace of undue faith in authorities in him. One must accept the truths of the ancients, but one man can never demand blind faith of another, and regard for our forefathers must not restrain us from using our own reason. The honor of art suffers thereby as much as does our own moral characters. If our minds, as Locke said, are possessed of the opinions of other people, even though they be true, we can not go a hair's breadth further in our own knowledge. On the other hand he perceived that the progress of a science is always due to the insight of a few preeminent men, and that their findings must almost of necessity be reduced to practical rules for the great mass of men, who think very little concerning what they see and read. In the belief that surgery would stand still if one were too vain to recognize, as an old man, the error of much that he had learned as a youth, he was honest enough to admit his changes of opinion, to which even the most clear-sighted and experienced men most often see forced upon them. It was even a greater mistake of that time to exaggerate the profession at the expense of truth, and to blindly believe whatever was maintained. If his opinion differed from that of other surgeons he contradicted them without injuring their reputation and standing. Mindful of the words of Seneca, that there is always something left to do, and that even after a thousand centuries no one will lack the opportunity to discover more. Pott was modest in differences of opinion and never forgot that those who come after us will always find plenty of occasion to wonder at the ignorance of their forefathers. He opposed quackery, which boasted especially in the treatment of hernia and fractures, and endeavored to enlighten the sick concerning their ills and the deceptions to which they were exposed.

Pott took single chapters of surgery and developed them into monographs in order to gain proficiency through detailed investigations. His style was masterly. He began with two excellent works on hernia (1756–57), in which he described inherent ruptures in which intestine and epiploön lay in the same sack with the testes, the various kinds of incarceration and the operation. Then followed investigations of the lachrymal fistula, in which the carious lachrymal bone was bored through with a curved trocar, and of rectal fistula (1761), for which he devised the so-called Pott's bistoury. His essay on fractures and luxations (1765), rich in new ideas, exercised the greatest influence in England; in it he discarded the too short splints and pointed out the advantages of a half curved position for the broken thigh. In his "Injuries of the Head" (1760–68) Pott showed an excessive preference for trepanation. He took up the diseases of the testes (1762–67) hitherto little known, distinguished the various kinds of hydrocele, and recommended the seton with the rejection of corrosives; he first described the chimney-sweeper's cancer (1775). In the operation for cataract he tried to again bring depression to its former importance (1775). Opposed to Bilguer, he upheld the necessity of amputations and set forth clearly the definite indications, as well as the most favorable time for operating. At the same time Pott published his most ingenious work, the discovery of caries of the spinal column, which received from him the name Malum Pottii ("Remarks on that kind of palsy of the lower limbs, which is frequently found accompanying a curvature of the spine," 1779). Pott's collected works were published by his son-in-law, Earle, in a complete edition (3 vols. 1790).

About this time Scottish surgery made a very marked advance, and this extraordinary impetus was due to certain entire families. There were four, the Monros, the Bells, the Burnses and the Hunters. The oldest, *Alexander Monro* (father), a pupil of Cheselden and Boerhaave, was professor of anatomy and of the surgical clinic in Edinburgh. He effected the establishment of the academic hospital there, and contributed much by his discourses, which were the first lectures of merit, much to the renown of the medical school established in the year 1720. A man of excellent character, full of ardent patriotism, he showed the warmest interest in the welfare of his city, became justice of the peace, director of the bank, and warden of the highways. He was the first to give lectures on comparative anatomy (1744). Besides many anatomic works in association with his sons, he declared himself with great vigor against the extraction of cancerous breasts, defended Petit's not opening the hernial sac and first suggested injections of wine in hydrocele. He insisted upon ligature of the arteries in amputation, and wrote a good book on caries. His surgical observations were collected in the "Medical Essays" of the college of Edinburgh physicians, as secretary of which body he published the first six volumes. His merit as a physician was not less eminent. The oldest son *Donald Monro*, as chief field physician in the Seven Years' War, reported upon camp fevers in the English military hospitals, and first recommended cooling remedies (poultices of ice, vinegar) in the treatment of aneurysms. He also prepared a complete edition of his father's works. To the youngest son *Alexander Monro*, professor in Edinburgh, we owe the first description of the bursa mucosa (1788), and the observation that the art. obturatoria sometimes encircles the neck of a crural rupture like a crown (1803); he made many anatomic investigations concerning the nervous system, the lymph glands and the testes.

Benjamin Bell, hospital surgeon in Edinburgh, established with his system of surgery (16 vols. 1783–88), the reputation of the second Scottish family. This compendium received the greatest applause at home and abroad, as there for the first time since Heister's book, was surgery treated in its entirety with the latest advancements. When A. G. Richter took the first volume in his hands he exclaimed "excellent! clean, instructive, practical, without hypotheses, and a man who has seen that whereof he speaks, and reflected upon that which he has seen." Benjamin Bell has the merit of the introduction of hollow splints (so-called English splints) in the treatment of fractures. His nephew *John Bell*, wrote on the nature and healing of wounds, and on the principles of surgery, portraying among other things the false traumatic aneurysm and the aneurysm per anastomosin very strikingly. His celebrated brother *Charles Bell*, in London, belonging rather to our century, besides producing many excellent observations and a work on operations, has reared an enduring monument to himself in the distinction of the posterior and anterior fibres of the spinal cord, and of the motor and sensory nerves.

In the Burns family, *Allan Burns* made himself known through a surgical anatomy of the neck, and the more illustrious *John Burns*. through a surgery and an anatomy of the pregnant uterus.

Among all the Scottish stars, the double-star of the Hunters shone the most brilliantly. The elder *William Hunter*, had studied theology five years when Cullen infused him with an interest in medicine and took him into his own house. After he had studied anatomy and obstetrics under Alexander Monro and Douglas, and had published his excellent researches on cartilages, he became the successor to Sharp in the anatomic amphitheater in London. He began with lectures in anatomy, which at that time no one else in London taught, but he always had a severe oppression of the heart when he spoke in public. He sojourned several months in Paris and Leyden, where Albin's injections made a great impression upon him. Hunter then instituted the most minute anatomic investigations, injected the veins of the testicle with quicksilver, concerning which there is a conflict of priority with the younger Alexander Monro, and later published an anatomy of the pregnant uterus with thirty-four magnificent plates, in which he for the first time described the membrana decidua (1774). He became surgeon in the Middlesex Hospital, then director of the lying-in house. Soon he was named among the best obstetricians in London at a time when Smellie, in spite of his European reputation, was very unpopular on account of his coarseness. In 1750 Hunter gave up surgical practice and became a doctor of medicine. For his natural history specimens which he had collected from his youth up, he built at an enormous expense a large museum, to which he annexed a private anatomic amphitheater where he delivered his lectures. It was possible for him to do this on account of the great wealth which he had accumulated through a wide practice among the nobility, and as obstetrician to the Queen of England. Hunter had a violent disposition, severe with himself and without consideration for others, therefore he was more honored than beloved by his colleagues. Unable to bear contradiction, he involved himself in many quarrels and even became estranged from his brother. Full of courage and strength of character he did not understand the art of pleasing, and brought even into the salon of the queen a candor very rare at court. Much afflicted with gout, he was overcome with pain in the midst of a lecture and fainted. During his illness his spirit was strong and he said to a friend shortly before his death, "If I could only hold a pen I would write down how easy and pleasant it is to die." In later years, rather a physician and obstetrician than a surgeon, he made himself a name in surgery by a distinction of true, false and mixed aneurysms, by the first description of aneur. varicosum, and by researches in the dilatation of the pr. vaginalis and the nature of congenital hernia. Charles Bell and Brodie worked under him, and as his most illustrious pupil, his brother John.

A *turning point in surgery begins with John Hunter*. However great is the progress of surgery in the nineteenth century, yet, without belittling the merits of our contemporaries, we must assert that in surgery so great and all-embracing a genius has been born to no other people, even to our own day. John Hunter belonged to the extremely rare phenomena which appear only at long intervals, and he was equally great as a surgeon, anatomist, physiologist, pathologist and naturalist. The power of his intellect was so extraordinary that he ranks with Aristotle, Harvey and Bichat. If one would draw a comparison between English and French contemporaries, he would place Desault along with Pott, and Bichat with John Hunter. But the former limited himself to mankind, while Hunter extended his researches not only to the laws of disease among men and animals, but over the entire realm of nature, organic and inorganic, and sought to fathom all forms of life to the farthest depth. The object which he had always before his eyes was the discovery of the laws of life; for only an intimate acquaintance with them can elucidate the causes of disease, without the knowledge of which no one can be a surgeon. His mind moved so freely that the greatest projects could not overpower him. "Thinking gave him pleasure," as he himself declared.

Born in 1728, at Long Calderwood, the youngest of ten children, John was lazy at school, often played truant and wandered about the country. At 20, when it is said he could scarcely read and write (?), he went to his brother William in London, to devote himself to anatomy. His progress was so great that in the following year he took pupils for instruction. After his surgical studies with Cheselden, he became an assistant in Bartholomew's Hospital, and then house surgeon in St. George's Hospital (1756). William placed great confidence in his brother's talent and made him an assistant in his lectures. Although in many things they were but little in harmony, yet the enthusiasm for anatomy was for a long time the means of keeping a certain concord between the two hot-heads. Later they were estranged, when William, full of passion, assumed the priority in their work on the structure and veins of the placenta and their connection with the uterus, and John would not publish a preparation pertaining to it. Their skill in the art of preparing specimens soon commanded general admiration. For ten years John dissected only human cadavers, and then he perceived that in many complicated relations only comparative anatomy could give satisfactory information. But in his animal dissections he never lost sight of the anatomy of man, but sought for general principles. Cadavers from menageries, and as many rare animals as possible, were bought. The consequence of his undue exertions was an illness which, after an attack of inflammation of the lungs, obliged him in 1760 to undertake a journey and go into the army. For three years he served as a military surgeon, in Jamaica and Portugal and in the Seven Years' War, and there gathered experience in gunshot wounds. Then he settled in London and began his instruction in anatomy, giving attention to practical medicine and surgery. In order to pursue anatomy undisturbed, he set up in Earlscourt, two English miles from London, a menagerie with many strange animals, a part of which he tamed and observed their habits. Once two leopards broke out of their cage and went into the court of the house, where the dogs immediately fell upon them. Hunter hastened to the spot, and saw that one leopard was about to climb directly over the court wall, while the other bit at the dogs. He managed to catch and lock up both in their cages again. His fondness for his menagerie remained with him even when he was an old man. The mildest animals were always his favorites, and he had many kinds of oxen brought from all parts of the world. Even in his sixty-fourth year (the year before his death) he often fought with a small ox, a present from the queen; once the animal overpowered him, until a servant sprang to his aid. While he came away from his sports with wild beasts with a whole skin, he wrenched his tendon of Achilles in dancing. Upon the recommendation of his brother, Hunter became directing surgeon in St. George's Hospital (1769), by which his private practice was greatly increased. He then began to lecture on theoretic and practical surgery (1773). Whatever he could spare of time and money was consumed in collections, for which he kept a designer in his house.

From sunrise till 8 in the morning he was an anatomist. A severe illness made it necessary that his brother-in-law, Everard Home, whom he had taken as a partner, should prepare a catalog of his specimens, as he feared for the existence of his family. But soon afterward he bought two houses in Leicester Square, and had a large building erected near by for his collections, at a cost of £3,000. It contained special halls for specimens, lectures, meetings of physicians and surgeons, rooms for anatomic works, printing and the sale of works. After the collections were put in perfect order in the beginning of 1780, he showed it twice a year, from that time till his death, to his colleagues, the nobility and other favorites. In this cabinet, which with the help of his friends, whom he had explore for him, had increased to about one hundred thousand specimens, he had endeavored to present nature in gradations from the simplest to the most complex organisms, so that the form and structure of parts could be compared in the specimens of the most widely differing animal species placed side by side. Everything was included in four main divisions (for the organs of preservation, motion, perception and reproduction). Besides dried specimens and specimens preserved in alcohol, the cabinet contained a large number of drawings, many rare stuffed animals, skulls, skeletons, pathologic specimens, abortions, bladder, kidney and intestinal calculi, insects, shells and a well chosen collection of minerals. After Hunter's death, the cabinet was bought by the state and turned over to the College of London Surgeons. His library was comparatively small and consisted chiefly of natural history works; one might have heard him say that he read no medical and surgical books (?); at all events he opposed much reading.

(To be continued.)

SELECTIONS.

Seasonal Influences upon the Infectious Diseases.—Dr. Andrew Davidson, at the last meeting of the London Epidemiological Society, read a paper on fluctuations in epidemic affections by seasonal influences, noting the variations in different countries and regions. Seasonal differences are frequently supplemented by parallel conditions of temperature and moisture of the soil, as was seen by the curves representing the single wave of cholera in the temperate climates and the single or double curves observed in India, where it was endemic, depending on the period of the rainy season or monsoons. In seeking the causes of these seasonal variations the diseases due to facultative saprophytes existing in the soil, such as cholera, enteric fever, malarial fevers, must be considered separately from smallpox and measles (obligatory parasites), which could be influenced by meteorologic conditions indirectly only, through the action of these on the resisting power or the habits and surroundings of the individual. Smallpox and measles had similar autumn, winter, spring and summer curves; and when introduced into a highly susceptible community spread irrespectively of season until the susceptible material was exhausted. The heights of the spring and autumn curves of measles were reversed in the English and Scotch towns, as well as in other countries. But comparing compound curves of series of years with single ones, it was seen that in most years only one was strongly marked.

"Habits of life, over-crowding in cold or wet weather, and the aggregation of children in schools, were factors not to be ignored, and as regards the latter it was a common occurrence in Germany and Poland for an epidemic of measles to be restricted either to the Christian or to the Jewish population. Smallpox and measles had one or two annual curves in Bagdad, but were wholly absent during the absolutely rainless summer months. In London the death rate from measles was highest in the second quarter in epidemic and in the fourth in non epidemic years; but Dr. Davidson could not say whether the prevalence or the case mortality corresponded to the number of deaths, though the Hamburg returns showed such to be the case in that town. He would suggest in explanation of many of these phenomena that in non-epidemic periods only the more susceptible were attacked, and that the virus passing through such individuals gained in intensity and the disease spread further; but that when, as in epidemics the more resistent were attacked it became alternated in them until it died out. Why epidemics should usually occur in winter and spring it was not easy to say. In Europe, India and America smallpox followed approximately the temperature curve, though it began to rise in winter when the temperature fell, but attained its maximum with the spring. The regular appearance of smallpox in the winter was ascribed by Flügge to the aggregation of persons indoors, the less frequent change of clothing, and the neglect of ablutions in cold weather; but this would not account for its maximum prevalence in early summer, and the conditions of domestic life in Europe did not apply to India where the same general curve was followed by the disease. It was easy to understand that facultative saprophytes multiplying in the soil were dependent on temperature and moisture, but these conditions could not directly affect those obligatory parasites whose soil was the living body; and these diseases followed their usual course irrespectively of climate and temperature. He had seen smallpox raging in Madagascar in 1868 when the temperature ranged between 90 and 100 F., and in 1870 it prevailed in the Hudson's Bay Territory with the thermometer at 4 degrees F. below zero. All alleged relations between the prevalence of measles and the temperature were true of particular countries only, and therefore could only be accidental. Weather conditions tending to induce catarrhs of the pharyngeal and the respiratory mucous membranes could not fail to render the individual more susceptible to infection from diseases, such as scarlet fever, diphtheria and measles, which were known to enter the body by these surfaces, and in like manner catarrh of the gastro intestinal canal favored the development of cholera and typhoid fever.—London *Lancet.*

Fallacies as to Birth Rate Statistics.—The latest compilation made of birth rate figures shows the rate in Nevada to be 16.30 per 1,000, so that its population would die out completely in less than one hundred years. Maine follows with a birth rate of 17.99 per 1,000, which gives its population about a century longer to exist. New Hampshire is third with 18 per 1,000, Vermont fourth with 18, and California fifth with 19 per 1,000, or nearly 12 per cent. less than the rate in France. This fact the alarmist statistician finds to be most striking, in view of the favorable climate, ample area and diversity of interests in the State. Following California is Connecticut, which has a birth rate of 21.3 per 1,000. Massachusetts has 21.5. Rhode Island has 22.5, a somewhat higher rate than the French, but still insufficient to prevent the extinction of the population within two or three centuries. Wyoming, with its 21.8, comes between Massachusetts and Rhode Island, while Oregon has a rate of 22.5. The conclusion drawn from these statistics is that within a period varying from sixty to two hundred years, according to circumstances, the population of New England and the Pacific coast will be replaced. This gives a good chance for the alarmist to arise and bemoan the condition of the Gaelic and Anglo-Saxon peoples, but the total extinction of these races in any given locality is not to be expected, the statisticians to the contrary notwithstanding. A low birth rate is not a mark of decadence or degeneracy anywhere; it is a mark of the disparity between the sexes in the population of any State or country. Statisticians make usually the mistake of estimating the growth of population not by the actual number of births, but by the relation which the number of these births bears to the total population. It is from this that they get their elusive "birth rate," and a little examination of the facts on which their last alarming bulletin is based will show this conclusively. In Nevada, by the last Federal census, the number of males in the State was 30,000; the number of females was 16,000. Thee were nearly twice as many males as females, but the statisticians, taking no regard of this disparity, based their estimates on the number of births to the total population, and thus arrived at the conclusion that the population of this State, as of other States on the Pacific, was dying out. In Oregon, by the last census taken by Federal authority, there were 180,000 males and 130,000 females, and in this State, for the same reason as in Nevada, the birth rate appears to be small. California is another State which the statisticians aver will at the present rate soon become depopulated. Theoretically, so to speak, it may; actually the population has increased from 380,000 in 1860 to 560,000 in 1870, 865,000 in 1880 and 1,210,000 in 1890—quite a rapid increase for a State which, according to the statisticians, is becoming depopulated. The reason of their error is the same in California as in Oregon and Nevada. By the last census the number of male residents of that State was 700,000 and of female residents 500,000.

For a similar reason, the New England States on the Atlantic seaboard have a low birth rate. The only difference is that in these States the disparity is on the other side of the column; there is an excess of female residents. In Rhode Island, for instance, by the last Federal census, there were 10,000 more female than male inhabitants in a State the total male population of which was 158,000. In New Hampshire the excess was 3,000, in Connecticut it was 7,000 and in Massachusetts it was 64,000. There is no danger of the depopulation of any American State. In some rural localities, it is true, population has fallen off, due to emigration to more fertile and productive regions, but if there be any pessimist about who is expecting the depopulation of any American State "within a period varying from sixty to two hundred years," he may better abandon his fears.—*New York Sun.*

PRACTICAL NOTES.

Radical Cure of Alopecia Areata.—Lorot proposes to remove the part affected, if of small extent, an insignificant operation, the scar being concealed by the hair. It is efficient in preventing contagion, especially in the army where the disease often assumes the proportions of an epidemic.—*Gaz. M. de Liège*, June 24, *Ind. Méd.*

Success of Methyl Blue in Albuminuria.—Lemoine describes the remarkable benefit he derived from methyl blue in seven cases of albuminuria in Bright's disease (*Nord. Med.*, July 1). It is soon eliminated through the kindeys without inconvenience, except possibly in some cases a slight smarting during miction, which can be prevented by adding a little nutmeg; 0.20 to 0.50 centigrams in twenty-four hours are sufficient.

Traumatic Endocarditis.—Litten asserts that traumatisms of the trunk may occasion grave endocarditis, even in the absence of any lesion of the skeleton or of the skin. There is an acute or subacute endocarditis of this nature which usually terminates in a chronic cardiac lesion (mitral or aortic insufficiency or stenosis). Recovery from this endocarditis is very rare. It sometimes assumes an infective character. The traumatism may lacerate the valves, especially the semilunar valves of the aorta, more rarely the mitral valve.—*Deutsche Med. Woch.*, June 10.

Functional Insufficiency of the Pylorus.—Zavadsky has recently treated three patients whose food passed into the intestine without remaining in the stomach at all. There was no gastro-intestinal disturbances, the appetite was good, but each meal was followed by a diarrheic evacuation, and bile seemed to be constantly present in the stomach. He secured prompt cure by administering nux vomica and iron, rinsing the stomach with water at 15 degrees C. every second day, hydrotherapy (river baths), and ordering that a belt be worn.—*Sem. Méd.*, June 9.

Results of More or Less Complete Obstruction of the Nose.—It has been suggested that many anemic conditions, etc., are to a more or less degree due to obstruction of the nose, producing numerous derangements, both in respiration, mastication and anatomic development, far more than has been hitherto realized. The organism does not obtain the requisite amount of oxygen, the secretion of saliva is affected, sleep disturbed, and the necessity of securing free nasal respiration is shown to be imperative, in an article in the *Presse Med.* of June 16, which describes the numerous evils of buccal respiration.

To Prevent Absorption of Perspiration in Orthopedic Corsets.—Vulpius has a tricot stuff made with a coating of the best rubber on one side. He applies this to the skin, or plaster cast, with the rubber side in smoothing out all wrinkles. It is perforated to allow for circulation of air. The corset is never worn next to the skin nor over the shirt, but over rather fine-meshed tricot underclothes which cling to the body without a wrinkle, and allow the air to circulate between it and the apparatus, which remains unaffected by the perspiration for two or three years.—*Cbl. f. Chir.*, June 26.

Adjustable Crutches.—Many persons temporarily lame do without crutches on account of the expense and trouble of procuring them, which much retards their complete recovery. To remedy this, Dr. O. Thilo has invented an adjustable, folding crutch which he keeps on hand and lends to such patients, and also recommends for hospital use and for growing children. The crutch is shortened or lengthened by moving the foot piece up or down in a metal shell that holds it; the cross pieces are secured with an iron rod, fastened with a copper nut at each end. The shoulder rest is a piece of webbing. The foot piece is made in three lengths for children, medium-sized and tall persons.—*St. Petersb. Med. Woch.*, No. 25, 1897.

Citric Acid in the Treatment of Wounds.—G. Müller had been treating a wound for four months that absolutely refused to heal in spite of massage, hydrotherapy, and the most approved methods of treatment, ancient and modern, when he casually applied the juice of a lemon to the wound and was surprised to note that it at once commenced to heal and complete recovery soon followed. He applied the juice of a lemon twice a day, with compresses of the same. The effect on other cases since has been equally favorable.—*Wien. Klin. Woch.*, June 10, from *Therap. Mon.*, No. 4.

Preventive Temporary Tampon in Operations on the Hollow Abdominal Organs.—C. Lauenstein has for years been using a simple process to prevent infection in his abdominal operations, which, as he has never seen it mentioned, he describes in the *Cbl. f. Chir.*, June 19. In a gastric fistula, for instance, from perforation of an ulcus ventriculi through the anterior abdominal wall below the left costal arch, after the contents of the stomach have been withdrawn, he packs the stomach with one very long strip of gauze, leaving the end hanging out. The suturing is done with the gauze still in the stomach, which prevents anything escaping from the stomach; as the suture progresses the gauze is gradually withdrawn until it is all out before the final stiches are taken.

Fractures of the Spine.—Poller's article on this subject is being copied extensively by the foreign exchanges, appearing originally in the *Arch. f. klin. Chir.*, Vol. liv, p. 289. He advocates forcible reduction under chloroform the moment the patient has recovered from the shock of the traumatism. He has thus cured six very serious cases. In twenty-two cases there have been no accidents; partial paralysis has never been transformed into total, and there have been no subsequent lesions of the spine. He agrees with Küster that it should be attempted even in old cases, resorting later to surgical intervention, if it fails. After reduction the patient is placed in bed and undergoes extension and counter-extension for several weeks. During this period he must be carefully watched to see that the bladder and rectum perform their functions properly, with massage, passive movements and electricity to combat paralysis and paresis. The mouth and skin should be carefully attended to, and before leaving the bed, at the end of a month or two, the patient should be suspended in a Sayre apparatus several times a day for fifteen or twenty minutes. He should then wear a Sayre corset and walk with a cane for a few days.

A New Throat Spray.—Dr. H. L. Armstrong, surgeon to the Manhattan Hospital, recommends the following prescription as almost a specific in acute inflammation of the upper air passages, both of the traumatic and nervous varieties:

Eucain	10 grains
Cocain, mur.	10 grains
Aq	6 ounces

Misce. Sig.—Spray every hour in the nose sufficient to be felt in the throat.

If the patient is taught to inhale while using this spray, so that the solution may be carried well within the larynx, it is far more beneficial than it otherwise would be. The advantage of this combination is that while cocain is a valuable remedy of itself the danger has been the liability of the patient to become addicted to its use. By the combination of eucain, which is a thorough local anesthetic in the nose, the nervous excitability produced by cocain will not be developed, thereby making the prescription perfectly safe, as nobody will contract the cocain habit by using this combination.—*New York Medical Journal.*

How to Apply the Tampon.—Dr. J. R. Dodge in *Annals of Gynecology and Pediatry*, article "Embryonic Miscarriage" gives advice as follows: "An ordinary bivalve speculum will answer every purpose; some prefer Sims' and the lateral position. In placing the tampon much care should be exercised in laying the foundation. The lint or cotton should be firmly packed around the cervix including the posterior cul-de-sac, and pledget after pledget should be laid on until the vagina is firmly and solidly filled. After removing the speculum several large pledgets of cotton placed over the external end and firmly held in position by a T-bandage secured by a strap around the body above the hips will complete the operation. Whatever is used in the formation of the tampon, whether it be cotton batting, lint, or strips of cloth, should be aseptic as far as possible, and the pledgets should be secured to a string with the end left protruding for its better removal." Remove tampon in six or eight hours if needed, but sooner if by cessation of pains it is evident the uterine contents have been expelled. "There need be no fear of internal hemorrhage," continued the writer, "for the uterine cavity is quickly filled and further oozing an impossibility. If the fetus has been expelled and the afterbirth still retained and not easily reached, the tampon may be replaced for a time. No physician should consider his patient safe until he has secured the removal of the secundines in any case of miscarriage which has advanced beyond the second month of pregnancy."

Comparative Diagnosis in Pulmonary Tuberculosis by the Roentgen Rays.—Stubert (*Medical Record*, May 22, 1897, p. 733) reports a series of seventy-three cases of pulmonary tuberculosis studied by means of the Roentgen rays and the fluoroscope. He found that in cases of slight infiltration of one or both apices there is a haziness or fog between the light and the observer, the clavicle in other instances appearing to have a gauzy veil thrown over it. When there is marked consolidation the transmitted light is relatively less, the edges of the clavicle are indistinct, or the bone may be invisible. When there is present the same pathologic condition at both apices it is an easy matter by comparing the two sides to decide at once on which the disease has made the most progress. Comparative shadows at the apices are generally seen more distinctly from behind than from in front, by directing the patient to bring his shoulders forward so as to separate as widely as possible the scapulæ and then placing the fluoroscope directly over the spinal column. Ordinarily a practiced eye can, by these methods alone, clearly distinguish areas of the most incipient infiltration, but if it is desired to be more accurate in defining their limits a metal rod may be placed evenly against the chest walls in front or behind and move up and down with the fluoroscope until its outline becomes more distinct, which will indicate that the upper and the lower borders of the consolidation have been reached. If a pencil mark be now made along the edge of the rod and subsequently percussion be practiced, the area of dulness will be found between these lines. In cases of complete dulness, say to the second interspace, with relatively less dulness for one or two interspaces below, a dark shadow will be seen over the first-named region, which will gradually shade off consecutively into haziness and normal reflex of light below, the area of haziness corresponding to the limits of relative dulness. In one or two instances slight haziness was observed in spots that at the time showed no other physical sign of disease, but where later disease developed. The results of the studies thus made may be summarized as follows: 1. Slight haziness indicates the beginning of tuberculous infiltration and may or may not be accompanied by dulness on percussion. 2. Decided shadows indicate consolidation, the extent of which is in direct relation to the comparative density of the shadows thrown on the fluoroscope. 3. Circumscribed spots of bright reflex, surrounded by narrow dark shadow rings, or located in the midst of an area of dense shadow, indicate cavities. 4. Intense darkness, especially at the lower portion of the lung, indicates old pleuritic thickening over consolidated lung tissue.

Treatment of Habitual Constipation in Women.—The constipation that results from lack of tone in the muscles concerned in defecation may have been caused by some lesion in child-bearing, or it may be nervous in its origin, which occurs also in men. The treatment of both is the same to bring these muscles up to tone. Pincus, the German gynecologist, accomplishes this by his "abstinence cure," which he claims will absolutely cure the most obstinate and inveterate cases of constipation from this cause. He first prepares the patient by a preliminary course: examining for uterine or adnexal troubles for which he orders vaginal injections at 38 to 40 degrees C., every day for a week, taking the temperature carefully and accepting the slightest rise in the temperature during this period as a contra-indication for the "abstinence cure." If the patient is nervous, he orders 1 to 3 grams of bromid a day, for a fortnight, with an enema of 2 grams of asafetida, and the yolk of an egg in 75 grams of water, or instead of an enema, a belladonna suppository (2 to 3 centigrams). If there are spasmodic contractions of the abdominal muscles a bag of sand is laid on the region for one to three hours a day or, better still, a kneaded mass of clay weighing from 500 grams to a kilogram. The continuous pressure of this fresh moist clay cures the spasms completely in three to eight days. In case of stercoral infection, the bowels are evacuated with injections of 7 per cent. salted water, or of pure oil, with a few doses of castor oil, avoiding all other purgatives. When all these precautions have been taken, he commences his cure immediately after a menstrual period. Every purgative or injection is forbidden, but there should be systematic massage of the abdomen, with Swedish gymnastics, and faradization of the intestines may be useful. The patient should be instructed to go to stool every day at a certain time, whether she feels any desire or not, and contract the levator ani morning and night thirty times, as if striving to restrain an imminent defecation. She should also roll around upon her abdomen before rising and retiring, for five to ten minutes, a bag filled with angular pebbles or scraps of iron. If the abdomen is flabby it should be frictioned with a brush, a wet compress applied at night, under an impermeable covering, and a belt worn. The treatment requires a month or two, including the preliminaries. The first spontaneous evacuation occurs in from three to ten days.—*Sem. Méd.*, June 9.

PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:
Per Annum, in Advance $5.00
Foreign Postage 1.75
Single Copies . . . . 10 Cents.
In requesting change of address, give *old* as well as new location.
Subscriptions may begin at any time and be sent to
THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 61 Market Street (Occidental Buildings), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, Venetian Building, Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the *Editor*, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

SATURDAY, AUGUST 7, 1897.

THE DIETETICS OF GLYCOSURIA.

In the treatment of diabetes mellitus the diet has been almost universally considered to be the one all-important matter. The disease, probably as little understood heretofore in its intimate nature as any one in our nosology, has been held to consist mainly in an abnormal excretion of sugar, and all other symptoms have been generally held to be dependent upon this. Just how excessive sugar excretion could produce the whole series of morbid phenomena no one has successfully endeavored to explain; the fact has been accepted and has been made the basis of the treatment. It has been practically assumed that the excess of sugar in the urine must be due, chiefly at least, to an inability of the system to dispose of sugar-producing foods, which normally constitute the larger bulk of our diet, and that the waste thus brought about was, if not the direct cause of all the morbid symptoms, at any rate an index to the gravity of the condition of the sufferer. The carbohydrates were therefore considered his greatest enemy and naturally to prevent their entering the system was the first indication for the treatment. It can not be claimed, however, that the prognosis of the disorder has been decidedly improved, in spite of the elaborate dietetic tables that have been contrived, or even that life has been materially prolonged by their means in the more advanced stages of the disease. It certainly is not made more endurable, even in the milder forms, where dieting does limit the sugar excretion. In the severer types where sugar continues to be excreted in spite of an exclusively proteid diet, the latter is certainly ineffective enough to have its usefulness questioned, and that being the case it may be asked if the stereotyped diabetic diet lists, impracticable as they are in some cases, and uncomfortable enough in all, should be adhered to. In fact, have we not followed a *post hoc, ergo propter hoc* reasoning too blindly in taking the excretion of sugar as the one important clinical symptom of the disease? The relation of sugar in the urine to the other symptoms is not so clear that we must necessarily assume it as causal and believe that with its reduction everything else in the morbid syndrome will mend. It may be, and probably is, only one incident of the general vice of nutrition that constitutes the disease and which in all probability depends primarily upon some serious disturbance of the central nervous system. PAVY has thought that this must be sought for in the vasomotor centers causing capillary dilatation and hyperoxidation of the blood, but, however it may be brought about, the probability of the original lesion of diabetes being in the nerve centers is one that should be recognized. How this is to be reached by treating the one symptom of glycosuria is not altogether demonstrable.

In the very thorough study of this subject by Dr. MUNSON, published in the JOURNAL a few weeks ago, he states "that there has apparently been of late an undercurrent of thought to the effect that possibly the complete exclusion of carbohydrates from the diet might not be an unalloyed blessing to the diabetic." His papers, however, form it is believed one of the most complete and thorough discussions of the subject and its literature in our language, and his conclusions, illustrated as they are by a case in his own actual experience, are certainly worthy of careful consideration. The facts that sugar is produced in the system by the splitting up of proteids, and that the most rigid exclusion of carbohydrates does not suppress its production or its excretion in extreme cases, that even the diabetic requires a certain proportion of sugar in his blood and possesses still a power of consuming it, and that this, if not supplied by carbohydrates, must be furnished by the albumins, are all very significant, and it is remarkable that more attention has not been given them before. In fact, aside from possible local effects upon the urinary passages, we know of no certain reason why a certain excess of sugar ingested should not be normally excreted without serious systemic disturbance, as is the case with many other substances: and this is the fact in ordinary dietetic glycosuria, which, considering the ordinary unlimited ingestion of saccharine substances, must be more frequent than is commonly supposed. In diabetes, however, this single symptom has masked the whole pathology of the disease, has become the disease itself in the mind of physicians generally, and therefore the sole object of the treatment. There is hardly another so striking example of this error of taking a part for the whole in all medicine—assuming these views to be correct.

Dr. Munson is of course not the first to except to the accepted views of the treatment of diabetes; there has been, as he says, an undercurrent of opposition to them for some time past. For example Saundby, at the International Medical Congress of 1894, read a paper favoring a change in the general practice of withdrawal of all carbohydrates from the diet of diabetics, and for allowing them so much of such substances as did not materially increase the urinary sugar, and others have published cases showing, like the one given by Dr. Munson, that the patient's general condition improves under such allowance. If this instead of the quantity of sugar excreted were generally taken as a guide, it is probable that there would be some change in the common views as to the therapeutics of diabetes. There would at any rate be probably less complications from the production of auto-intoxications by a diet that is abnormal in health, and that can hardly be expected to be all that is demanded by the disordered organism.

Even if Dr. Munson's opinion, that the sufferer from diabetes requires sugar in his diet even more than a person in perfect health, be not accepted as too extreme, there is still evidence enough to warrant a very material alteration in the hitherto accepted views of the necessary dietetic treatment of the disease. If possible, we should aim to meet the neurosis itself, and not be led aside by a single predominant symptom, and this can not well be done by still further crippling an already depleted system.

THE GENERAL PRACTITIONER HIS OWN HEMATOLOGIST.

In these busy days, a period which in the history of medicine, will be known as "The Age of the Specialist," the general practitioner must hail with delight a branch of the science so rapidly opening up before him. Let us see what can be done with only a microscope, the possession of which instrument should be the first aim of every physician.

A drop of blood from the lobe of the ear, hastily touched by the center of a clean cover-glass, is deposited on a warm, highly-polished slide and a single layer of corpuscles thus spread. With a little experience one can readily tell if the drop is more concentrated than normal or is hydremic. Examination with a one-twelfth inch oil immersion will determine the relative size of the red corpuscles, their shape, the approximate number of white to red, and detect the presence of parasites; a few minutes' search may clear up a case of malaria which has been puzzling the diagnostician many weeks. To a favored few will it be fated to study the filaria sanguinis hominis or the spirochæte of relapsing fever. Should our patient live at a distance, that need not deter one from an examination of his blood; a drop of blood drawn between two cover-glasses and allowed to dry can be "fixed" and kept in equal parts of absolute alcohol and ether until ready for examination. These specimens are first stained. Staining three to five minutes in a ½ per cent. alcoholic solution of eosin, washing off excess and counter-staining a few seconds (10 to 15). in a weak aqueous solution of methyl blue will be adequate for almost every case. Under this process the red cells are stained red and the white blue, the nuclei of the white cells (also of the red if nucleated reds are present), being especially prominent.

Eosinophilic and neutrophilic granules are also stained a red color, the shades depending on affinity for eosin and the length of time the various stains have been used. The Ehrlich "triple stain" is most suitable for staining leukemic blood.

In the stained specimens another factor may be taken into consideration, the "differential count." A ratio of the varieties of white corpuscles having been fixed upon as normal, it was thought that a considerable variation from this standard might point to some pathologic condition, and such has been found to be the case in tuberculosis and other wasting diseases, where the lymphocytes are greatly increased in percentage. The method is to count 1,000 white cells, noting in the appropriate column whether lymphocyte, large mononuclear leucocyte, polynuclear neutrophile or eosinophile. These terms will become perfectly familiar after a few hours' hard study of a well-stained specimen.

In addition to the above, the presence of bacilli, cocci, myelocytes, nucleated red corpuscles, and other pathologic products may be determined by careful search.

So much then of blood-work can be done by every physician or one familiar with the microscope; no other instrument is necessary. How much more might be accomplished by the judicious expenditure of a little time and money in the Thoma-Zeiss "counter," the Fleischl hemometer and other so-called instruments of precision. An exact knowledge of the number of white and red corpuscles per c.c., the percentage of hemoglobin, the specific gravity of the blood, is of paramount importance in the diagnosis of leukemia, pernicious anemia and chlorosis, while the treatment of these diseases follows the diagnosis as but one of its corollaries. A favorable prognosis can often be made in pneumonia by the presence of a considerable leucocytosis, while the latest achievement in hematology, the blood-serum method of diagnosis of typhoid fever as introduced by Pfeiffer and Widal, will give an impetus to this infant science along a new line that will soon cause an examination of the blood to become as routine a procedure as an examination of the urine.

SWIMMING AS AN AGENCY IN HYGIENE AND THALASSO-THERAPEUTICS.

The late Sir Henry Holland, who died at an advanced age, declared in his memoirs that his life had been exceptionally happy, and that he attributed much of this to the two months' holiday that he took every year. Although we can not all be court physicians, yet most of us acknowledge the wisdom and propriety in the suggestion as to holiday diversion. Sitting in stuffy offices during sweltering weather, waiting for patients who perhaps never come, or traversing sun-baked streets in his daily rounds, the fancy of a weary physician, like that of a starving man at a barmecidal feast, turns to the fresh blue sea with its foaming rollers tossing upon the beach, and his mind teems with recollections of Newport, Narragansett or some less favored places, that since the time Chryses wandered disconsolate and silent by the sounding main, the sea and its shores have been resorted to for health and recreation, while numerous writers of more recent date have extolled the ocean as a health resort, and have sung the praises of sea bathing.

Nearly every one knows the rejuvenating effect of a trip across the Atlantic, and the new lease of life imparted to many by a short sojourn at the seaside can not be over-estimated. All things considered, no form of outing is superior to a course of thalasso-therapeutics, and of all the great adjuvant means or agencies that may serve alone or collectively to this medication none surpasses swimming. If the individual who goes in for this sort of thing does not swim; he should learn and be made to recognize the necessity of an easily acquired art, the educational, hygienic and therapeutic value of which is beyond question.

In the British Isles enthusiasm for this delightful amusement and useful accomplishment grows each successive year, and it is taught and practiced to an extent little realized by Americans. Indeed it is generally agreed among populace, educators and physicians, that the advantages of learning to swim when young are incontestable. Dr. Clement Dukes, physician to Rugby school, in "Health at School," says, "I lay special stress upon the value of swimming, baths and bathing. Every school that can possibly manage it should have a place in which the boys can learn and practice swimming."

At many of the large schools in England lads are obliged to pass in swimming before they are allowed to go out in boats. This rule, established at Eton in 1840, has been effectual there in the prevention of drowning, only one case having occurred since that time, although the swamping of boats has been frequent. A yearly average of 150 boys learn to swim and pass the test.

At Harrow, where Lord Byron of Hellespontine renown and Sir Robert Peel learned to swim, the well-known "Duck Puddle" is the favorite place for learning and practicing the natatory art. The knowledge here acquired has served many in good stead in after life, a notable instance being the son of Sir Robert Peel when shipwrecked by night in the Mediterranean.

At Rossall, every boy, unless specially exempted on medical grounds, must practice swimming.

At Uppingham, one of the largest schools, swimming is considered of the highest importance.

Swimming is also recognized officially as a subject of instruction in the elementary board schools of England, and the London School Board recognizes swimming as a subject under their code.

Numerous swimming clubs exist all over Great Britain, among them clubs for women The Woman's Union Swimming Club was highly commended by a woman physician a few years ago in one of the medical journals, and at least one English girl holds a record for a ten-mile swimming event.

This aquatic zeal, like the morning drum beat of the race who are its chief exponents, appears to have encircled the earth, for in distant Australia and far-away New South Wales, similar enthusiasm prevails as in the mother country. The records of the swimming associations in these colonies are among the most creditable. In New Zealand the swimming clubs as a body are endeavoring to bring about provision by education boards for organized instruction in swimming, to classify swimmers uniformly, to induce the State to issue certificates of proficiency, to promote a more general acquaintance with the steps taken to restore animation and effect rescues, and to that end give greater encouragement to long distance events and to life-saving competitions.

Great loss of life from drowning is one of the strongest arguments in favor of swimming. In the Journal, June 27, 1889, under the head of "Bathing and Boating Accidents," attention was called to the frequency of drowning, and in treating the medicolegal relation of death from submersion, the chapter in Witthaus and Becker's "Medical Jurisprudence," refers to modern statistics, which show the great development of this class of emergency. We need, moreover, only take up our morning paper at this season to see frequent accounts of drowning, which are all the more sad for the reason that most of them arise from inability to swim in circumstances where only a moderate knowledge of the art or even a few strokes would have sufficed to save life. To be sure, good swimmers are sometimes drowned, but exceptional occurrences of the kind in no way invalidate the benefits of swimming. in view of the multitudinous number who are saved through knowing how to swim. Ample proof of this statement is within the knowledge and experience of nearly every one who has lived near the water. We know personally some very poor swimmers who have thereby saved their lives, and of some very valiant ones, distinguished for saving the lives of others. A few years ago an English ship off the Newfoundland Bank was run down at night by a steamer and almost instantly sunk, when the thirteen men of the crew jumped overboard. Of this number the only one drowned was a Russian who could not swim. The others were rescued through ability to swim until picked up. At Montreal in 1893 several yachts carrying thirty-five people were capsized by a sudden squall and sunk. Every one on board, including one woman, could swim. All were rescued after the accident.

Similar instances, citable to indefinite extent, are as numerous as the works on balneology and hydrotherapeutics, subjects that in late years have been studied with such profundity as to give rise to the brief and precise term, "medical thalassology." Questions of the kind have been discussed at two congresses of thalasso-therapeutics within the last four years, one at Brussels and the other at Boulogne-sur-Mer. The discussions at these meetings show pronounced unanimity as to the action of swimming and sea bathing upon the organism, the consecutive effects leading to decongestive action of the internal organs, tonification of the skin and muscles, and in general to a tonic and vivifying action.

Briefly speaking the hygienic indications are that children profit more from thalasso-therapeutics and support it best. Young girls at puberty with retarded menstruation from atony of the genital organs, overworked school boys, young women suffering from atonic sterility and people suffering from general fatigue or languishing health are greatly benefited, but the very old profit less.

As a curative means it is incontestable that the methods of thalasso-therapeutics are in the first line as regards lymphatism and scrofulo-tuberculosis with all its manifestations, and in rachitism it is the preferable mode of treatment. Other therapeutic indications are found in the seminal losses dependent upon genital abuse, in the menstrual troubles of young girls at the epoch of puberty, leucorrhea, chlorosis, metrorrhagia; in the diseases of women, as dysmenorrhea, amenorrhea, different lesions of the uterus, uterine neuralgia, sterility, gastralgia and dyspepsia connected with menstruation. It is, moreover, indicated in convalescence and in chronic maladies, as diabetes, obesity, impaludism, provided that the patients have enough reactive force.

The marine cure is also beneficial in chronic respiratory ailments, as bronchitis, asthma, whooping-cough, emphysema and even in pulmonary tuberculosis of torpid form if treated at a Southern resort. Chronic indigestion, neuralgia, dry skin diseases and chronic rheumatism likewise may be added to the list.

The exercise of swimming besides acts as a counterpoise to the more sedentary employments and physically less active life of women, and if nothing more could be said in its favor, it is of inestimable value in banishing permanently the "backache" and migraine so prevalent in the sex. Increased activity of the heart and lungs, the action of muscles not ordinarily used, the tonic effect of cold immersion, exposure of the naked body to actinism of the sunlight and an exhilaration akin to flying are conditions that conduce to the elimination of urea and the abolition of dyspepsia and insomnia, and are superior to the tent-cure, to massage, electricity or drugs. From the less stable equilibrium of the nervous system, women are, as a rule, extremely sensitive to the tonic influence of cool or cold water, and any thing which promotes this habit in them should be specially encouraged. It is authoritatively stated that there is no class of diseases in which the effects of thalasso-therapeutics are more conspicuously beneficial than in that termed nervous from whatever cause proceeding. Hence neurologists recommend swimming or sea bathing as one of the best adjuvants in the treatment of functional nervous diseases and have the satisfaction to get most encouraging results in hypochondria, hysteria, chorea and in sexual neurasthenia.

A therapeutic agency so potent for good is not without its dangers and contraindications. If used indiscriminately it may become a species of quackery which destroys life. There are, of course, many weak people whose chest organs are in such a condition that they should not venture to swim. Heart disease, aneurysm, Bright's disease, organic disease of the central nervous system and advanced tuberculosis are contraindicated, nor should the subjects of gout or eczema with secretion be advised to take the cure.

Knowing the reconstructive power of the agencies of which we write to be undisputed, and being aware of the fact that it is easier to increase health than to diminish sickness, these remarks were meant to apply in a hygienic rather than a therapeutic sense.

The neglect to learn swimming in childhood is responsible for many flabby hearts, weak lungs and torpid minds. From the view-point of physical education it is clearly of the highest importance that all young persons, especially girls, be taught swimming, since we are dependent upon them for the make-up of the next generation. The smattering of physiology with other things of doubtful utility now taught girls at school is absolutely worthless, and according to high medical authority, even hurtful. A prominent New York physician on a late visit to a well-known girls' college was invited to attend the class of physiology. The instructress, proceeding to demonstrate the uterus and ovaries, used a cat for the purpose. The class dismissed, the doctor happened to look at the cadaver, which, to his utter astonishment, proved to be a "tomcat."

Less physiology of this kind, less piano, less algebra and other inanities that go to make up the curriculum of a girls' school, may well be put aside for more wholesome and useful instruction that shall contribute to domestic and family happiness by returning to more rational conditions. Then half the chronic diseases resulting from or aggravated by artificial habits of civilized life will disappear; domestic infidelity and divorce proceedings will be less frequent, and the increased prevalence of sexual perversion, existing at present as the disturbance of a badly balanced nervous system, will be among the diminished things of the past.

THE REPORT OF THE BRITISH VACCINATION COMMISSION.

We are glad to have at last the actual report of the British Vaccination Commission before us, more or less imperfect abstracts of which have been published.

After seven years work, during which time the Commission held 136 meetings, examined 187 witnesses, and investigated six epidemics, a voluminous report is offered. The Commission was appointed in May, 1889, and among its members are some of the most prominent physicians of Great Britain. The objects of the Commission were to investigate:

1. The effect of vaccination in reducing the prevalence of and mortality from smallpox.
2. What means other than vaccination can be used for diminishing the prevalence of smallpox, and how far such means could be relied on in place of vaccination.
3. The objections made to vaccination on the ground of injurious effects alleged to result therefrom, and the nature and extent of any injurious effect which do in fact result.
4. Whether any, if so what means should be adopted for preventing the ill effects, if any, resulting from vaccination; and whether, and if so by what means, vaccination with animal vaccine should be further facilitated as a part of public vaccination.
5. Whether any alterations should be made in the arrangements and proceedings for securing the performance of vaccination, and in particular, in the provisions of the Vaccination Acts with respect to prosecutions for non-compliance with the law.

The report first reviews the subject of smallpox historically, and reiterates the accounts of the horrible devastations of this scourge. It is recalled that in Europe in the last century, smallpox killed 500,000 people annually; that it caused half the deaths of children under 10 years; that to it was attributed one-half to two-thirds of the blindness; and that it was severely epidemic about once in three years. No class of people was exempt. Six members of the family of WILLIAM III. died from smallpox, and the monarch himself was permanently marked. Illustrative of its great prevalence in England, it is stated that in the town of Chester, in 1774, with a population of nearly 15,000, and without any exceptional sanitary disadvantages as such affairs stood in those days, 93 per cent. of the inhabitants had had smallpox.

The practice of inoculation until its prohibition in 1840, and the gradual popularity of vaccination until the principle of compulsion, first introduced in the Act of 1850, are reviewed. Further legislation founded on the assumption of the efficacy of vaccination was instituted in 1867, 1871, 1874 and 1879. Arguments are advanced that conclusively show the enormous decrease of the disease after the acceptance of vaccination, and that also prove that the decrease was not due to the great decline in the practice of inoculation, nor to improved sanitary conditions. There is no evidence of a noticeable decline of smallpox in the unvaccinated countries during the same periods; and there was no lessening of the mortality from other infectious diseases such as measles, scarlatina and whooping-cough.

Inquiry into recent epidemics in England definitely proves the protective influence of vaccination, and the greater the number of vaccination marks the greater the protection. After reviewing the evidence the Commission find:

1. That vaccination diminishes the liability to be attacked by the disease.
2. That it modifies the character of the disease, and renders it less fatal and of a milder type.
3. That the protection it affords against attacks of the disease is greatest during the years immediately succeeding the operation of vaccination. It is impossible to fix with precision the length of this period of highest protection. Though not in all cases the same if a period is to be fixed, it might fairly be said to cover in general a space of nine or ten years.
4. That after a lapse of the period of highest protective potency, the efficacy of vaccination to protect against attack rapidly diminishes, but that it is still considerable in the next quinquennium, and possibly never altogether ceases.
5. That power to modify the character of the disease is also greatest in the period in which its power to protect is greatest, but that its power thus to modify the disease does not diminish as rapidly as its protective influence against attacks, and its efficacy during the later periods of life to modify the disease is still considerable.
6. That re-vaccination restores the protection which lapse of time has diminished, but the evidence shows that this protection again diminishes, and that to ensure the highest degree of protection which vaccination can give, the operation should be at intervals repeated.
7. That the beneficial effects of vaccination are most experienced by those in whose case it has been most thorough. It may be fairly concluded that where the

vaccine matter is inserted in three or four places it is more effectual than when inserted in one or two places only, and that if vaccination marks are of an area of half a square inch, they indicate a better state of protection than if their area be all considerably below this.

The Commission believes that there is no evidence to substantiate the statement that vaccination has increased the mortality from tabes mesenterica, scrofula, pyemia, bronchitis, diarrhea and skin diseases. The possibility of infection with syphilis and erysipelas is acknowledged, but the sum total of the real dangers of vaccination is insignificant when compared to the enormous good of vaccination.

To afford absolute security against the communication of syphilis, calf-lymph is recommended; and the Commission advise that so long as vaccination is compulsory, the patient or the parent should be allowed the choice of calf-lymph or humanized lymph. To further diminish hostility to vaccination, it is recommended that there should be an extension of age within which vaccination is required, and that vaccination vesicles should not be opened without adequate reason.

Immediate notification of the disease, and hospital isolation of the patients and isolation for sixteen days of all those who had been in immediate contact with them, offers the only substitute for vaccination; and in reviewing this subject the Commission can see nothing to warrant the conclusion that in Great Britain vaccination might be safely abandoned and replaced by a system of isolation.

Further recommendations are:

That power should be given to the sanitary authorities to give compensation for loss of wages occasioned by isolation; that notification of smallpox should everywhere be made compulsory; that increased powers should be given to local authorities with regard to common lodging-houses; that re-vaccination should be encouraged without being made compulsory; and that persons committed to prison by reason of non-payment of penalties under the vaccination laws should no longer be treated as criminals.

The Commission offers no satisfactory substitutes for the Compulsory Acts. Any half-way measures seem to allow so many avenues of avoiding compliance with the Acts that they would soon become virtually inoperative.

The report of the majority is signed by eleven of the thirteen members of the Commission. Mr. JONATHAN HUTCHINSON and Sir WILLIAM HUNTER, possibly the most prominent and influential members, do not sanction any relaxation of the existing compulsory laws, and even recommend compulsory re-vaccination. Four members dissent from any form of compulsion, believing that the offer with appropriate arguments should be made to the patients and parents, leaving them free to accept or reject. Two alone of the Commission, Dr. COLLINS and Mr. PICTON, question the efficacy of vaccination.

CORRESPONDENCE.

The Organization of the Missouri Board of Health; A Letter to the Governor by C. H. Hughes, M.D.

ST. LOUIS, MO., May 25, 1897.

HON. LON. V. STEVENS, GOVERNOR OF MISSOURI:

Dear Sir:—Yours of the 22d inst. is received. My idea about appointments on the State Board of Health from the standpoint of a chief executive acting for all the people would be that all interests should be represented in proper ratio. The preponderating interests should be the majority of the people through the medical men who represent them. Every lawfully recognized medical interest should have a place on the Board in proportion to ratio of population. The people who employ the regular medical methods of advanced modern medicine being preponderatingly ascendent, should have the majority. Regular modern medicine is in no sense a theoretic school of medicine, nor the "old school," nor allopathic school, as the homeopathists derisively term it. Its votaries administer treatment on the allopathic, contrapathic, homeopathic or any other principle. It is simply rational medicine founded on observation, experience and the study of the human machine and how to regulate it, in health and disease, so as to keep it running best and longest.

A century ago the practice of medicine was as different from the practice of today as methods of transportation are as compared with those of today. The regular profession itself was divided between theorists. The theory of Hahnemann was in vogue as that of Paracelsus, a regular physician, only Hahnemann cut away and made an exclusive system of practice and adopted the infinitesimal dosage idea.

Laboratory study and biologic investigation, vivisections and animal experimentations, supplanted all the theories with facts of physiologic and chemic research and made a new medicine, and the regular practice is the newest of all schools of medicine, if a practice that accepts everything that cures, unhandicapped by any theory of its action, can be called a school. We ignore the term as a misnomer, as we reject the epithet, allopath, as too restrictive and sectarian, as homeopathy is. Scientific investigations, continuous observation and enlightened experience guide the best minds in regular medicine. It has learned some things that are good from homeopathy and adopted them and some things that are bad and rejected them. Personal proving without physiology and pathology is fallacious. Medicine is a developing science and its practice an evolution. No broad-minded observer, no matter how he starts or what he professes, if he has a naturally qualified medical mind, can honestly continue through life a sectarian physician—an exclusive pathist of any kind. There is but one place for a physician and that is unhandicapped and without a sectarian designation, free to choose from all sources in the regular profession.

I do not approve of persecution or censure of the sectarian physician, nor of excluding him from fellowship with regular physicians, if he drops his trade mark, as many do and more are now doing. Men become sectarian physicians as they join churches, because of environment, wife, mother, etc., and when a woman's arms are about a man what can he do?

I hope you will constitute that board as it seems to me you are in duty bound to do, recognizing all interests. It is not with you a question of schools but one of the people.

I object to the procedure at Fulton, not because *the hom-*

eopathists should not have a place to be treated in but because regulars who represent so large a part of the people should not be turned out to make a place for them and because the act is in its nature *ex post facto*, the patients having been sent there for regular treatment. As a physician I should object to real, honest old time homeopathy because of its fallacy and inadequacy, not because some superior homeopathic physicians do not show more skill than some inferior regular physicians, for medical practice is much in the man and his personal judgment.

Before you finally act on this subject I hope you will fully inform yourself as to the status of this sect with reference to onward-marching modern medicine that has done in the last third of a century and is now doing so much for mankind, and not be influenced by the stale old cries of old school, nauseous drugs, allopath, etc., against the most advanced of all scientific pursuits of our day. Modern hygiene, neurology, bacteriology, quarantine, the study of the causes and prevention of disease, antiseptic surgery, etc., all belong to regular medicine. All that homeopathy accedes to or uses is taken from the work of our laboratories, clinicians and savants. While a sect in medicine or religion should be recognized by the State, it should not be placed in a position to dominate the non-sectarian.

On reflection, I think it would be an unjust stab at the large college interest in the State and at the honor of college men, not to allow it representation on the Board. It strikes me that one or two fair-minded men might be selected from all interests involved. I think the college men know best what the schools want and if no one college should have a majority fairness in action would be assured. Regular medicine is undoubtedly entitled to larger and permanent representation, not alone because it is now the newest, most advanced and most liberal school (if you insist on the term), and the most truly eclectic, for it gathers freely from every source that may enlighten or cure, but from a sound political standpoint, viz., it represents the greater number of the body politic. More of the people prefer it and employ regular physicians than the sects in medicine and, hence, as their chief executive representative you are in duty bound to regard their wishes and interests. You are the people's spokesman and servant in the the premises. Yours very truly, C. H. HUGHES, M.D.

The Treatment of Typhoid Fever.—A Reply to Dr. John Eliot Woodbridge.

RICHMOND, VA., July 19, 1897.

To the Editor:—The JOURNAL of July 17 contains a communication from Dr. John Eliot Woodbridge criticising my paper published in the current number of the JOURNAL, June 3. I would pass this communication unnoticed, but the writer overlooks my disavowal in my paper of any intention to treat him with discourtesy, and descends to offensive personalities. I pass these by with the single criticism that Dr. Woodbridge has misunderstood me.

I read the paper in the Section of Practice at the recent meeting of the ASSOCIATION. Dr. Woodbridge was a member of that Section, and I do not understand *why* he should have waited until now to criticise my position. If not present at the time my paper was read he was when the discussion came up. I was not present during the few remarks he made, and which are reported in the proceedings. His criticism of the earlier part of my paper is not worth noticing. I leave it to a discriminating profession whether a room will be better disinfected by the methods suggested in my paper, or by his method of "sending a stream of formaldehyde gas through the keyhole, and the next night use the room with safety as a surgical ward." What does he send it in with? He should tell us all about it. It seems to me a consistent suggestion, and as gassy as his other assertions. But I am not inaccurate, nor have I misrepresented him. Messrs. Parke, Davis & Co. have scattered broadcast over the country a pamphlet purporting to be extracts from Dr. Woodbridge's paper read before the Section on Practice of the AMERICAN MEDICAL ASSOCIATION, and other societies, and if he is disingenuous enough to take my quotations in my article and compare them, he will find the quotations accurate to the letter, and I again assert that such assertions do not commend themselves to the mind of any physician familiar with the causation and pathology of typhoid fever. There is a question of accurate diagnosis when he tells us the patient must "be put on the treatment when first seen; if you await pathognomonic symptoms, it will not always succeed." Strange he has no criticism of my quotations from Tyson and I. C. Wilson. I am in very good company with these gentlemen, and Osler and many others of the best authorities the land over. I deny that I have made any unjustifiable or unprofessional attack upon members of the AMERICAN MEDICAL ASSOCIATION. There are hundreds of good men who fail to analyze cases and treatment, and specious statements, made like those in Dr. Woodbridge's papers, find many followers, and accurate observations *are not made*. I want to *know* from these gentlemen how this treatment cures. I want them to tell us something of the nature of the disease. and how, when the poison has been multiplying and developing the clinical conditions present in typhoid fever, all of these morbid conditions can be aborted. Grant for argument's sake that every case was correctly diagnosed, I commend to his consideration the following, freely quoted from the authors to whom they are accredited, and ask him how he gets over these undeniable facts:

"The typhoid bacilli gain access by the intestinal tract and enter the lymph structures of the intestines, developing there, elaborating toxic principles, which give rise to the constitutional phenomena. The bacilli are not found in the fecal discharges in the early course of the disease, but first appear about the time of the necrosis of the lymph elements. *These facts justify* the assumption that *the bacilli do not develop, as do those of cholera, in the lumen of the gut.*" (Italics mine.)

"Infiltration attains its maximum development at the end of the first week, and the tenth day of the disease. Rapid necrosis now takes place, and the sloughs separate about the latter half of the second and the first of the third week." "The mesenteric glands show histologic changes similar to those in the intestinal structures. . . . Other lymphatic glands may undergo enlargement; notably those in the fissure of the liver." "Spleen enlarged in over 90 per cent. of cases. Investigations of Walter Reed, at Johns Hopkins, show that the lymphomata of Wagner are in reality areas of necrosis (in the liver); as to whether due to the direct action of the bacillus, or caused by the toxalbumins, has not yet been definitely determined. Reed considers the latter most probable. In the kidneys, similar changes to those described in the liver have been found. When suppuration occurs, miliary abscesses are found, and typhoid bacilli have been found in these minute collections of pus." ("American System of Practice," Loomis-Thompson, pp. 173-179.)

The *above* sustained by Tyson: "There are instances of the general infection of the body, etc.," see Osler, second edition, p. 11. See also clinical history and pathology described in Wood and Fitz.

Now, sir, I commend to Dr. Woodbridge and his endorsers the above authorities, and deny, backed by such unquestioned authority, that it is possible for him, or any other man, to abort typhoid fever by seeking by such depressant methods as he recommends, to take out of the system the infectious principle. There is a period of several days to several weeks of prodromes, *the patient is not seen until after* the system is too fully under the influence of the disease to have it cut short.

It is true, I do not possess a knowledge, "either theoretic or practical," in line with the Woodbridge methods, but a large experience for thirty years, and the small mortality of 6 to 7 per cent. in the treatment of typhoid fever contradicts the statement of a failure to understand the disease from every standpoint. I did not deal with statistics in my original paper, because I did not think it required, except in the discussion of the Woodbridge method. I leave it to any candid man to read the testimonials of the Woodbridge treatment and compare them with those of any quack nostrum, and draw the distinction if he can. It is only necessary to refer to Dr. Woodbridge's paper of July 10 of the Journal. Dr. Woodbridge charges me with gross misrepresentations. I venture to assert that in my own city and State my reputation for fairness and truth, for accuracy of observation and progressive professional methods, is fully equal to Dr. Woodbridge's, and will be attested not only by my professional confrères, but by many students whom I have taught.

Dr. Woodbridge's assertions are fallacious, based on faulty principles, and he, not I, shows gross ignorance and assumes a knowledge of the pathology and nature of the disease which *nothing* he has written sustains, and finds its outcome in a treatment so unscientific as to make it the solemn duty of every lover of his profession to denounce it as a piece of routinism and quackery. He cries out because he is hurt. I leave him to a discriminating profession.

Very respectfully yours, J. M. Upshur, M.D.

National Examining Board.

Lyle, Minn., July 27, 1897.

To the Editor:—Has there ever been anything done to foster the idea of or create a *National Examining Board*? I believe a movement of this nature would meet with the support not only of every reputable practitioner but of the present *State Boards* as well. Nothing is more commendable and more enthusiastically supported by the best class of physicians than the increasing standards being required in several States to obtain a license to practice medicine. A rigid examination should be passed before a license is granted; but the rank injustice of the present system is apparent to anyone who will give it a moment's thought. If a physician is located near the line as I am here he will be required to pass an examination in two, three or possibly four States to practice in one district. If one should desire to change his location to another State, there is the examination again. It is not only a nuisance and an expense, but requires a thorough review of technical points that are never used in practice. I would like to add to your cry for a "Department of Public health" and a "National Examining Board." S. H. Rabuck, M.D.

Answer:—For articles on National Examining Boards see the Journal, vol. xviii, May 15, 1892, p. 610; vol. xxvi, May 16, 1896, p. 950.

Is Diabetes Increasing?

Philadelphia, July 31, 1897.

To the Editor:—In an editorial in one of your recent numbers the stand is taken that diabetes is increasing in England and America, because the reports from city hospitals show an increase. I will not attempt to dispute the figures, but I only wish to point out a possible cause for the increase.

Diabetes is supposed to be common among Jews. In the last fifteen years there has been a great influx of Jews from Russia to both England and America, and as a rule they remain in the cities. To my own personal knowledge the patients who present themselves at the dispensaries of the large Philadelphia hospitals are largely from this class, consequently this fact alone may serve to increase the number of cases of diabetes in London, New York and Philadelphia.

No doubt other diseases peculiar to races will be found to be on the increase from like causes. At least, immigration is a factor that must be considered in a matter of this sort.

Very respectfully, M. V. Ball, M.D,

BOOK NOTICES.

Text-book on Mental Diseases.—By Theo. H. Kellogg, A.M., M.D., late Medical Superintendent of Willard State Hospital, etc., etc. Octavo, 792 pages, illustrated by original sphygmographic tracings and photographs of the different types of mental disorder. pp. 776. Extra muslin, $6.00.

It is a pleasure to review this work, which is dedicated to the distinguished editor of the *Medical Record* of New York, as follows:

"George F. Shrady, A.M.,M.D., in special appreciation of his persistence and able advocacy of progressive and scientific methods of treatment of the insane; in recognition of his useful and distinguished professional career as Medical Editor and manager of State Hospitals, and visiting and consulting Hospital Surgeon; and as a personal tribute to his sterling traits of character."

The author's long experience as Superintendent of Hospitals for the insane and in the treatment of mental diseases has given him a right to have an opinion on the diagnosis and treatment of the various types of insanity.

The work opens with a chapter on the history of insanity. It also includes a historic sketch of the general condition and treatment of the insane, and the summary survey of the evolution of the science of psychiatry. The chapters are divided as follows: 2. Statistics of Insanity. 3. Nosology. 4. Etiology. 5. Termination of Mental Disorders. 6, is divided into three sections under the general head of Psychical Symptomatology. Chapter 7, on Somatic Symptomatology, is divided into eleven sections, viz.:

1. On the Defects and Pathological changes of the Osseous System.
2. The Muscular System.
3. The Vascular System.
4. Changes in the Cutaneous Surface.
5. Splanchnological.
6. Nutritive, Secretory and Trophic Disturbances.
7. Disorders of Cerebral, Spinal and Nervous System.
8. "On the Pathology of Insanity," is divided into two sections, viz.: 1. On the Pathogenesis of Mental Disorders. 2. Pathology of Insanity, the Macroscopical Changes and the Microscopical Changes.
9. Diagnosis of Insanity, including feigned Insanity and the deduction of various forms of malingering.
10. Prognosis of Insanity.
11. Treatment of Insanity, including prophylaxis.

Part 2 is on the special groups and typical forms of insanity, and contains twelve chapters, viz.: 1. Insanity from general organic arrest of development. 2. Insanity from Neuropathic State. 3. Insanity from Established Neurosis. 4. Insanity from Physiological Crisis. 5. Insanity with General Systemic State. 6. Insanity with Definite Lesions of the Cerebral, Spinal and Nervous System. 7. Psycho-Traumatic Insanity. 8. State of Depression. 9. State of Exaltation. 10. State of Mental Weakness. 11. State of Stupor. 12. State of Impaired or Suspended Volition.

It will be seen that the treatise is at once systematic and comprehensive, and we have no hesitation in commending the book as an entirely trustworthy volume in the study of mental diseases. The work is destined to take high rank as a standard treatise on the subject.

The National Confectioners' Association of the United States.

This little volume published in 1897 from the office of the *Confectioner's Journal* is a handsomely printed volume, on good paper. It contains extracts from Constitution and By-laws, list of officers and members and organization and object of work, pure food and pure candy laws of each State in the Union as they were in force April 1, 1897.

On account of these laws being so collected the book should have a permanent place in the library of every sanitarian as a reference volume.

System of Diseases of the Eye by American, British, Dutch, French and German Authors. Edited by WILLIAM F. NORRIS, A.M., M.D. and CHARLES A. OLIVER, A.M., M.D. Vol. ii, 214 illustrations, pp. 556. Philadelphia: J. B. Lippincott Co. 1897.

This magnificent system has been given a handsome setting by the publishers; inset plates, beautiful paper, and excellent illustrations make it a pleasurable task to give it notice. This part of the system is given to chapters on examination of the eye, school hygiene, statistics of blindness and antiseptics.

The contributors to this volume are J. Snellen of Utrecht, Holland, L. Laquern, M.D., Strasbourg-en-Alsace, Germany; George M. Gould, M.D., A.M., Philadelphia, Pa.; Edward Jackson, A.M., M.D., Philadelphia, Pa.; Adolphe Javal, Jr., Paris, France; William S. Bennett, M.D., New York City; George T. Stevens, M.D., Ph.D., New York; Herman Wilbrand, M.D., Hamburg, Germany; William Thompson, M.D., Philadelphia, Pa.; S. D. Risley, A.M., M.D., Philadelphia, Pa.; I. M. Hays, A.M., M.D., Philadelphia, Pa.; J. A. Andrews, M.D., New York City; Jos. McFarland, M.D., Philadelphia, Pa.; Samuel S. Kneass, M.D., Philadelphia, Pa.

The articles of Snellen, Laquern and Wilbrand have been carefully translated. As all the articles in the volume are written especially for it, the whole appears as a new contribution to the subject.

Dr. Thompson in his article on Color Blindness, in writing of the main impetus of the practical side of this question omits reference to the pamphlet of Professor Henry of the Smithsonian Institution, and does but scant justice to the work of Jeffries. (Page 316.) And he omits all reference to the work of the United States Government in the examination of pilots, the initial step of which was taken by the editor of this journal, then at the head of the Marine-Hospital Service in 1880, in first giving facilities for voluntary examination of seamen. The matter was subsequently taken up and made compulsory by the Board of Inspectors of Steam Vessels; this was done before the system was introduced on railroads, although no one would suspect it from reading the article of Dr. Thompson. The instance quoted on page 330 of the Steam Tug Lumberman, originally appeared in the Marine Hospital Service Report and the finding of the color-blind pilot was the direct result of the orders issued in 1880. Jeffries' book as mentioned in Thompson's article refers to the second edition only; the book was originally published in 1879, and at that time there was nowhere in this country a systemized test for color blindness of the personnel of any railroad employes or the merchant marine in the United States. With the exception of the historical matter, however, the article is an excellent one, although it may be doubted whether the Thompson method of using the worsteds is any improvement over the original plan of Holmgren.

It is an ungracious task to refer to any defect in so excellent a work, but our duty is clear. The second volume of the system contains internal evidence that it will undoubtedly last for many years as the standard American work of reference on the eye. The other two volumes of the system, we are informed will speedily follow.

The Eye as an Aid in General Diagnosis, A HAND-BOOK FOR THE USE OF STUDENTS AND GENERAL PRACTITIONERS. By E. H. LINNELL, M.D. Philadelphia: The Edwards & Docker Co. 1897.

The object of this book is to show that the examination of the eyes affords valuable aid in the diagnosis of diseases of the nervous system as well as of numerous affections of other organs and to induce the practitioners to pay more attention to this too much neglected subject.

Possessing the experience of a general practice of twenty years and fifteen years of experience as an oculist, the author is singularly well qualified to produce a book, which though written from the standpoint of a specialist, is perfectly suited to the understanding of the general practitioner. The first part of the book is devoted to the eye symptoms of nervous and constitutional diseases. The author taking up the various parts of the eye in their anatomic order from the lids and conjunctiva to the retina and optic nerve, points out the local affections and the general diseases they are symptoms of. This part closes with a very practical reference list of diseases arranged alphabetically, with their more or less characteristic eye symptoms.

The second part, treating of the reflex neuroses, deserves our highest praise; it is an admirably well written statement of the etiologic relation of certain ocular affections to the functional nervous diseases and, on the other hand, of the dependence of certain functional eye troubles upon reflex actions emanating from distant sources of irritation.

The third part discusses the ocular affections of toxic origin; and closes with a very complete index, which is of the greatest value in a book of reference. We wish this book would find a place in the library of every progressive physician; it would then not fail to fulfil its mission to impress upon the practitioners the diagnostic importance of the symptoms in general diseases.

Suppression and Prevention of Leprosy. By ALFRED S. ASHMEAD, M.D., late foreign medical director Tokay Hospital, Japan. Paper. Illustrated, pp. 96. Norristown, Pa.: Herald Printing and Binding Rooms.

The author briefly considers the history of the microbe, the non curability of leprosy and the conditions predisposing to leprosy, going more into detail on the horrors of leprosy, necessity of absolute isolation and the idea of a national lazaretto. Touching on the relation of the church to leprosy, leprosy in Japan and the advantages of asepsis, he concludes that nothing "has been done for the leper through the discovery of the bacillus, or in any other way. . . . That consequently anybody who *seriously*, *truly* wishes for the abolition of the terrible disease, can hope for nothing else but isolation, and isolation absolutely alone."

Schaefer's Course of Practical Histology. By EDWARD ALBERT SCHAEFER, LL.D., F.R.S., Jodrell Professor of Physiology in University College, London. Second edition; 12mo. 307 pages, 59 engravings. Cloth, $2.25. Philadelphia and New York: Lea Brothers & Co. 1897.

It has been some time since the first American edition of this work appeared and the reader who peruses it will recognize as careful condensation and method of arrangement as in the first edition. New illustrations have been added, with description of new processes necessary to bring it to include the result of recent progress in histology.

The student will find this book one of the most trustworthy condensed guide books on the market.

Sixteenth Report of the State Board of Health of Wisconsin.

The report covers the biennial period ending Sept. 30, 1896. Besides containing the "General Report of the Board," "Report of the Secretary," "Report of the Inspection of the Different State Institutions" and "Report of Delegate to the Conference of State Boards," we note "The Purification of the Water Supply of Ashland by Sand Filtration," and "Enteric or Typhoid Fever," articles of much value. The report also presents a list of health officers of local boards, and extracts showing the general health of the different cities and towns. Dr. U. O. B. Wingate is secretary of the Board.

Transactions of American Pediatric Society. Eighth Session, held at Montreal, Canada, May 25, 26 and 27, 1897. Edited by FLOYD CRANDALL. 1896.

This volume contains the minutes of the eighth annual meeting, address of the president, various papers read, and the report on antitoxin, which we have heretofore printed. These papers have been printed in abstract in the JOURNAL and in full in the *Archives of Pediatrics*. The illustrations are excellent and the mechanical execution of the work fair.

PUBLIC HEALTH.

Health of Denver, Colorado.—The Bureau of Health reports twenty-seven cases of infectious and contagious diseases reported in June 1897, with fourteen deaths therefrom, as compared to thirty-nine such cases reported in May, with nine deaths therefrom. The total number of deaths, in Denver, for the year ending June 30, 1897, was 1,696, a rate of 10.60 per 1,000 per annum.

Who Pays for Preventing Spread of Contagious Diseases?—The Indiana statute provides that the Board of Commissioners of each county shall constitute a Board of Health *ex officio* for the county, "whose duty it shall be to protect the public health, by removal of causes of diseases, when known, and in all cases to take prompt action to arrest the spread of contagious diseases, to abate and remove nuisances dangerous to the public health, and perform such other duties as may, from time to time, be required of them by the State Board of Health pertaining to the health of the people." In carrying such purpose into effect, according to the meaning of the statute, the appellate court of Indiana says, April 2, 1897, it might become the duty of the county, under particular circumstances, to supply medical service, medicines, nurses, shelter, fuel, food and raiment for patients taken for the time being under the control of the board, and placed in such situation that such provision would be a necessary part of the protection of the public health. At the same time, it says that it does not mean to indicate what would be the proper conclusion in this regard in other cases. It only decides that where, as in the case of Board of Commissioners of Jay County v. Fertich, the patients remain in their own home, and are not shown to be indigent, but, for all that appears, are amply able to pay for medical treatment of the disease with which they are afflicted, and the case differs from other cases of illness in the fact that the disease is contagious, and that, therefore, for the protection of the public health, they are quarantined, the only expenses which should fall upon the county, within the intent of the statute, are such expenses as are properly attributable to measures taken for the prevention of the spread of the disease. It draws the line at requiring the afflicted persons to defray expenses not incurred for their own benefit. And it suggests that the particular items of expense for which allowance should be made will vary with changed circumstances.

Compulsory Vaccination of School Children.—The question whether or not the State Board of Health, or the school directors of a district, acting under its orders or otherwise, had any power to impose, as a condition of the admission of children to the public schools, the requirement of vaccination, was considered by the supreme court of Illinois, in the case of Potts v. Breen. Its decision was that neither had the power. No such power had been conferred on the State Board of Health, it said, unless by the broad and general language of the statute which provides that "The State Board of Health shall have the general supervision of the interests of the health and life of the citizens of the State." But that was not intended to confer plenary powers on the board. It had and could have no legislative power. Its duties were purely ministerial and the foregoing provision could not be held to confer that broad discretionary power contended for, to prescribe conditions upon which the citizen of the State might exercise rights and privileges guaranteed to him by public law. As recently held by the supreme court of Wisconsin in a similar case, the powers of the State Board of Health are limited to the proper enforcement of statutes, or provisions thereof, having reference to emergencies requiring action on the part of the agencies of government to preserve the public health, and to prevent the spread of contagious or infectious diseases. The right or privilege of attending the public schools is given by law to every child of proper age in the State. Whether the legislature has the power to make vaccination a condition precedent to the exercise of this right or not, was not decided. It could not be supposed that it had undertaken to do so by mere implication. No one would contend that a rule enforcing the use of antitoxin as a condition precedent to the admission of a child to the public schools, would, as the law now is, be valid, however fully satisfied by learning and experience that it would prevent the spread of diphtheria. And when vaccination is compulsorily applied it must, like all other civil regulations, be applied in conformity to law. In cases of emergency it might be proper, in the exercise of the police power of the State, to exclude children from the public schools on the ground that they refuse to be vaccinated. Undoubtedly, also, children infected or exposed to smallpox may be temporarily excluded, or the school may be temporarily suspended. But this power ceases when the necessity ceases. Nor have school directors and boards of education authority to exclude children from the public schools for refusing to be vaccinated, unless in cases of emergency.

The "Animal Odor" of Milk.—Dr. Huff of Rome, N. Y., has recently reported to the Board of Health of that city upon the commonly unnoticed elements of contamination of milk within the dairies themselves. He says: "Consumers of milk have often asked me what was the cause of a peculiar odor, characteristic of new milk, that is usually considered as being one of the necessary elements of milk. My observation leads me to believe that nine-tenths of the so-called 'animal odor' is caused by imperfect circulation in the skin of the animal and by particles of dung falling into the pail of milk. Cattle are milked in stables reeking with filth, and with swarms of flies congregating upon the strainer that is placed upon the can, and the milk is filtered over the carcasses of drowned flies that may have just been feeding upon the sputa of a consumptive or regaling themselves upon other putrid or offensive matter, and their excrement is washed into the can of milk to be sold to the public. The udder is frequently washed by dipping the hand into the milk that is in the pail, or by milking into the hand and then washing the teat with the milk. Very seldom will one see the udder washed with clean water or wiped with a clean cloth. And it is said that in cases after the cow had put her foot into the pail half full of milk, the milk went in with the rest and the consumer was none the wiser. A very small percentage of dairy farms are supplied with water of good quality and sufficient quantity.

"As a healthy cow will consume from 60 to 100 pounds of water per diem, the influence that a supply deficient in quantity and quality would have upon the milk is obvious. It is not an uncommon thing to see the drainage from the stable passing into the stream from which the cows drink. Cows confined to the stable require a space of 800 sq. feet each to obtain sufficient oxygen to aerate the blood properly, but we usually see cattle huddled together in as close a space as possible, generally allowing each cow about 275 to 300 square feet, where they are compelled to breathe and rebreathe the contaminated atmosphere because the dairyman informs us he can get more milk from them if they are kept close together. The majority of stables are built as cheaply as possible, and are roughly finished inside and out, furnishing nooks and crannies for dirt to locate and to propagate disease. The floor frequently consists of 12-inch planks laid side by side, just where the hind feet of the cows are placed and the milker stands when milking, and a trench about a foot wide behind the cows for the excrement to fall into. There is not one stable in a hundred that has any way of flushing, and no greater percentage has any system of drainage. There are stables that have stood for years upon the same ground and have contained hundreds of cows, and all the liquid manure made in them has been allowed to soak into the ground and there remain. There has been so much said about milk containing germs of disease that it seems almost unnecessary to mention the fact, but we are so forcibly reminded that dirt and filth are the abiding places of disease and that cleanliness is the surest guide to health, that your attention is again called to it and you are again warned of the danger that exists. The dairyman is a citizen and entitled to all kindness and courtesy, and in making changes in the arrangement of stables and methods of handling the product, we should remember that we are in a position to be of great assistance or to work a cruel hardship. We should endeavor to make changes in a kindly manner, but with all the firmness that a public servant should have. No honest dairyman should or would object to a strict observance of sanitary measures, but the dishonest dairyman must be controlled."

NECROLOGY.

Hugh Flournoy McNary, A.B., M.D. (*vide* Journal, p. 1045), born at Princeton, Ky., Jan. 15, 1837; son of Dr. Thomas Logan and Maria Louisa Flournoy McNary. He graduated from Cumberland College, Princeton, in 1857. He studied medicine in his father's office, and attended a course of lectures at the Medical Department of the University of Louisville, 1860-61. Proceeding to Harvard University, he graduated in the Medical Department of that institution in 1863. He entered the United States army volunteer service as assistant surgeon at Camp Nelson, Ky. He served subsequently at the General Hospital at Jeffersonville, Ind. He and Dr. Middleton Goldsmith accompanied the expedition of General Banks in the Red River campaign. He left the service of the United States army on Aug. 31, 1865, and settled in Louisville, for the practice of his profession. In 1867 the Governor of Kentucky appointed Dr. McNary physician to the Western Kentucky Lunatic Asylum at Hopkinsville. Tiring of this service, he resigned in 1869, and returned to Princeton, the home of his youth, where he was elected city and county health officer. He had a large practice, and was devoted to society work, rarely missing a meeting of his local or State society; and frequently attending the American Medical Association as a delegate from Kentucky. In the quiet pursuit of his practice at Princeton, he ceaselessly pursued the study of his profession. In 1895, when Wm. O. Bradley was elected Governor of Kentucky, he appointed Dr. McNary superintendent and physician in charge of the Central Kentucky Asylum for Lunatics. Dr. McNary entered upon the duties of this office with a full sense of his responsibility. He looked into every detail of the management of the institution; inaugurated new methods of general management; classified and arranged each subordinate department, and suggested vast and important enlargements and improvements in the buildings of the institution, which were rapidly advancing to completion, when a fatal affection of the heart seized him, and on May 12, 1897, he breathed his last in the home of his brother-in-law, Judge Darby of Louisville. No man in the medical profession of Kentucky was more widely and favorably known. He was a most genial companion, fond of good fellowship, and indulged in no dissipations. Those who knew him throughout his whole professional life, miss him sadly. He was a scholar gifted with superior powers of expression, an easy and fluent writer, yet he contributed but little to the literature of medicine. In the meetings of our local and State medical societies he always contributed something of interest, and was a debater of superior ability. He was a man of superb and magnetic presence, more than six feet tall, with a beaming countenance and sparkling eye, which always attracted attention in any company. He was modest as a girl, generous and charitable; a veritable philanthropist whose noble deeds of charity will be sadly missed by large numbers of the poor and afflicted.

William Thurman, M.D., New York City, July 21. He was an alumnus of the College of the City of New York (1860) and of the College of Physicians and Surgeons, New York (1864); also a Fellow of both the Academy of Medicine and the New York County Medical Association. After his service on the House Staff of the New York Hospital, he became House Physician of the Northern Dispensary and subsequently attending surgeon of the Children's Free Hospital St. John's Guild.

John James Hervey Love, M.D., New York University Medical College, 1855, died suddenly at his home in Montclair, N. J., July 30. He was an alumnus of Lafayette College, Easton, Pa., class 1851, and during the war while serving as surgeon of the 13th Regiment New Jersey Volunteer Infantry was also surgeon of the 3d Brigade, 1st Division, 12th Army Corps, March, 1863, and surgeon 1st Division, 12th Army Corps, Army of the Potomac from August, 1863, until his honorable discharge Jan. 23, 1864. As a man of affairs and a practitioner, he was widely known.

Charles O. Baker, M.D., Auburn, N. Y., died July 16. He was born in 1852, was graduated in 1874 from the College of Medicine, Syracuse (N. Y.) University, practiced general medicine until 1891, when after a special operative course under Lawson Tait, he limited himself to abdominal surgery.

John Condict Pennington, M.D., College of Physicians and Surgeons, New York, 1875, died in New York City, July 27. He was a son of Dr. Samuel H. Pennington of Newark, N. J. For some years his name was in the list of physicians at Colorado Springs.

Louis F. Kiefer, M.D., College of Physicians and Surgeons New York, 1886, a resident practitioner of New York City, died there July 23, aged 45 years. He was unmarried and a member of several fraternal societies.

Greig Smith, M.D., Bristol, England, Member of Royal College of Surgery of England; Surgeon of Royal Infirmary, Bristol; Professor of Surgical Pathology, Medical College of Bristol; Medical Examiner of the University of Aberdeen, and well known by his works on abdominal surgery. His treatise on abdominal surgery, published in 1887, placed him in the first rank.

William T. Hobbs, M.D., Mound, Ill., July 18, aged 58 years.——Simson P. Hubbard, M.D., Taunton, Mass., July 20, aged 70 years.——John Le Crone, M.D., Effingham, Ill., aged 81 years.——John Wesley Noyes, M.D., Racine, Wis., July 24, aged 76 years.——C. S. Park, M.D., Mt. Pleasant, Mich., July 25.——W. A. Russell, M.D., Pittsfield, Mass., July 19.——Eugene F. Sanger, M.D., Bangor, Me., July 24, aged 68 years.——D. C. Scull, M.D., Lebanon, Ind., July 24.——William W. Skinner, M.D., Forrest, Ill., July 25, aged 27 years.——A. M. Stebbins, M.D., Fertile, Minn., July 21.——Edward Storck, M.D., Buffalo, N. Y., July 26, aged 66 years.——H. B. Smith, M.D., McAlester, I. T., July 17.——Judson J. Taylor, M.D., Syracuse, N. Y., July 26, aged 59 years.

SOCIETY NEWS.

Central District Medical Association of Iowa.—At the annual meeting of the Central District Medical Association of Iowa, held at Boone, Iowa, June 15, 1897, the following resolutions were adopted and ordered printed and a copy furnished each member of the society:

Whereas, Complaints of various characters and kinds have been made to the Committee of Ethics and the Board of Censors, therefore be it hereby

Resolved, That it shall be deemed cause of expulsion or bar to admission for any member of this society either directly or indirectly to consult or hold counsel with any irregular practitioner of medicine. G. H. Stanger, Secretary.

Boone, Iowa, July 1, 1897.

Rocky Mountain Doctors.—Delegates from the inter-mountain States and Territories organized the Rocky Mountain Interstate Medical Association at Salt Lake City, July 21. The officers chosen were: C. P. Hough of Salt Lake, president; C. K. Cole of Helena, vice-president; Clayton Parkhill of Denver, second vice-president; E. Steuver of Wyoming, secretary and treasurer. The meeting for 1898 will be in Denver during the meeting of the American Medical Association.

MISCELLANY.

Personal.—Dr. Edward G. Janeway has been elected President of the faculty of Bellevue Hospital Medical College, N. Y., to succeed Dr. William T. Lusk, deceased.

The Missouri Medical League has been organized at St. Louis. Its object is "to unite doctors of good standing for mutual protection" and to collect evidence of hospital and dispensary abuse and to exclude well-to-do persons from medical charities.

Tuberculosis in Birds and Fishes.—Recent investigations have established the fact that the tuberculosis of birds and fishes is the same as human tuberculosis, but that it can not be transmitted to man owing to its lesser virulence in the cold-blooded animals.—*Bull. de l'Acad. de Méd.*, June 29.

International Prize Competition.—The *St. Petersb. Med. Woch.* announces that the Moscow "City Duma" has founded a prize as a memorial of the International Congress, to be awarded tri-annually for the best work on the subject of public health, prevention of epidemics, etc. It will consist of 5,000 francs and be awarded irrespective of nationality.

"The Pennsylvania Medical Journal."—At its recent meeting, the Pennsylvania State Medical Society made the *Pittsburg Medical Review* the official organ for publishing the transactions of that Society, and the *Review* becomes with the July number, the *Pennsylvania Medical Journal.* All success to the *Review* under its new name!

Correction.—Dr. E. A. de Schweinitz of Washington, D. C., says that in his article on "Antitoxic Serum for Tuberculosis" (JOURNAL, July 17, page 114) that the reference to Dr. Trudeau should be changed as follows: "Dr. Trudeau noted a reduction of temperature after the use of this serum in one case, and Dr. Stubbert, etc."

A Mild Sensation in Paris.—The Hospital Aubervilliers recently lost through thieves a number of rabbits kept for the culture of diphtheria, cholera, bubonic plague and other germs. The bacteriologists averted a panic by the assurance that if the rabbits were sold to be eaten there could be no danger if they were well cooked. So far as can be learned the advice was considerately taken.

Tattooing, according to the *Press and Circular*, was an ancient method of treatment, the forerunner of scarification. A mummy discovered in Egypt in 1891, that of a priestess of Hator, some five thousand years old, displays traces of a methodical tattooing of the abdomen, suggesting that the cause of death was generalized peritonitis. Tattooing is still resorted to in Egypt as a remedy for periostitis, arthritis and synovitis, and even for migraine and neuralgia.

Damages for a Cough.—The market value of a cough was the question submitted to the Birmingham (England) County Court. A barrister sued a railroad company for £50 for discomfort suffered by smoking being allowed in a waiting-room at a station and in non-smoking carriages. The smoking aggravated the barrister's cough, and he was awarded £10.—*Law Notes.*

Mexican Physicians en route for Moscow.—The *Normania* which left New York July 27 numbered among the passengers the following: Francisco Vasquez Gomez, Dr. Ismael Prieto, Dr. Carlos Tejedo and wife, Dr. I. Urquiza and family, Mr. Lorenzo Chavez, Dr. Alonzo, Dr. Eduardo Liccaga and family; Dr. Francisco P. Bernaldez, Roberto Garcia, Dr. Jose Terres and family, Dr. Domingo Orvananos, Dr. J. L. Vallejo, Mr. Salvador Echagray, Dr. Manuel Toussaint, Dr. Porfirio Parra, Dr. Francisco Hurtado, Dr. Vergara Lopez, Dr. M. Carmond y Valle, Mr. Luis S. Carmona, Rafael Caraza and wife, J. M. Bandera, Dr. Eduardo Garcia, Dr. Antonio Carbajal, Alberto Losa y Gomez, Dr. Angel Gavino, Dr. Tomas Noriega, Dr. Rafael Riba, Nicolas Ramirez Arrellano, Dr. Salvador Garciadiego and Dr. Morales and family. The remainder of the party are on their way from Mexico. Some of the delegates will proceed to the Moscow convention by way of Berlin and others by way of Paris.

The Human Lorgnette.—Gaston Seguy, the first man in France to repeat the experiments of Roentgen and who has been most of his time occupied in the laboratory of Le Roux in studying vacuums and the properties of cathode rays, has constructed what he styles a "human lorgnette," which will show the organs of the human body with minute exactitude. The French Department of Customs has applied the instrument with signal success in the examination of sealed packages suspected of containing dutiable articles. The apparatus in question is not larger than a parlor stereopticon and is as readily handled. In a comparatively small compass Seguy has put the various components of his contrivance, such as electric storage cells, transformers and tubes, all of which are essential for the X-ray.

Heredity and Trauma in Intestinal Carcinoma.—Boas has been collecting statistics on these points and finds heredity active in only three out of sixty-two certain cases (forty-nine men and thirteen women). In nine the carcinoma could be traced directly to a trauma with four years to half a year as the limit of intervening time. He states that carcinoma may exist for years without developing, as is proved by the unsuspected carcinomas found at necropsies, and he is inclined to ascribe a latent stage—a year and a half at longest—to cancer of the stomach. Some influence, usually of a mechanical nature, starts them into active growth, and this applies especially to the gastro-intestinal canal. But trauma of a member would not suffice; there must be some *commotio* of the whole organism or of the entire gastro-intestinal tract or part of it to start a carcinoma to proliferating from this cause. The age is also important, the younger the individual the more probable the connection.—*Therap. Woch.*, July 4.

Medical Schools in Denver.—The supreme court of the State of Colorado has forbidden the University of Colorado from carrying on any part of its Medical Department in Denver because the constitution locates the University itself at Boulder. In consequence of this the members of the Faculty resident in Denver have resigned and the larger portion of them have united with the Medical Department of the University of Denver. Among those who have thus strengthened the Denver Medical School are Dr. H. T. Pershing in diseases of the mind and nervous system; Drs. S. G. Bonney and H. B. Whitney in medicine; Dr. Charles A. Powers in surgery; Dr. Walter A. Jayne in gynecology; Dr. George B. Packard in orthopedics; Drs. L. E. Lemen and J. W. O'Connor in clinical surgery; Dr. T. E. Taylor in clinical obstetrics and Dr. John Chase in clinical ophthalmology. The faculty of the school has been further enlarged by the election of Dr. P. V. Carlin in obstetrics, Drs. W. H. Bergtold and W. B. Fenn in pathology and Dr. Carroll E. Edson in therapeutics.

Sterilization of Surgical Instruments.—G. Denigès has combined Marechal's suggestion that instruments can be protected from rust indefinitely by the addition of a small quantity of some alkaline (*vide* JOURNAL, Vol. xxvii, p. 547), with the use of a powerful antiseptic, and announces that instruments thus treated are absolutely sterilized while they suffer no injury, even if left for months in the antiseptic solution. His formula is mercuric cyanid 2 to 5 grams in 1 liter water, to which are added 5 grams sodium borate or carbonate. It is also remarkably effective and harmless for disinfecting the hands. As the efficacy of sodium bicarbonate has been recently proclaimed in the treatment of purulent wounds (JOURNAL, Vol. xxviii, p. 655), he adds that this might be substituted for the borate. The present low price of mercuric cyanid would be still further reduced if there were more demand for it. Its toxicity has been much exaggerated, as 1 molecule, Cy_2Hg, only contains 1 5 cyanogen to 4·5 mercury. It is much superior for the purpose to the bichlorid; it is less caustic, and does not affect the albuminoids, which are coagulated by sublimate. He hopes to see his formula generally adopted in outside antisepsis and hospital practice.—*Bull. de la Soc. de Pharm. de Bordeaux*, June, 1897.

Validity of Minnesota Law as to Committment of Insane.—The supreme court of Minnesota holds, in the case of State v. Kilbourne, that subchapter 14, of chapter 46, General Laws of 1889, did not authorize the probate court to proceed to find a person insane, without bringing him into court, or giving him notice of the proceedings being taken against him, or an opportunity to defend, and is not for any such reason unconstitutional because not providing for due process of law. Properly construed, it says the law simply authorizes the court to dispense with the issuing of a warrant when the alleged insane person can be brought into court without it. The court further holds that in order to collaterally impeach the judgment of the probate court in proceedings to commit an alleged insane person to the hospital for the insane, the want of jurisdiction must affirmatively appear by the record itself. The fact that it does not appear that any warrant had been issued for the arrest of the alleged insane person, or that he was present in court at any time during the proceedings, is not sufficient to impeach the judgment or show want of jurisdiction. The record of proceedings in the court does not show want of jurisdiction by its own mere silence.

The Morbid Histology of Epileptic Idiocy and Epileptic Imbecility.—As a result of histologic studies, Andriezen (*British Medical Journal*, May 1, 1897, p. 1081) has found in cases of epileptic idiocy and epileptic imbecility, a diffuse sclerosis or overgrowth of the neuroglia fiber cells in the brain substance and a co-extensive change in the nerve cells. The latter was of two kinds: 1. Defective development (fewness and slenderness) of protoplasmic processes. 2. Increase in amount and diffusion of pigment throughout the cell body, especially its basal part, and a displacement of the nucleus toward the apex of the cell. Later changes were a gradual destruction and atrophy of the nerve-cell processes, consequent on or co-extensive with the further overgrowth of the glia (sclerosis), until whole groups or islands of cells might be so destroyed. There is thus a common pathogenic basis for epileptic idiocy and epileptic imbecility, and for focal epilepsy occurring in the child, namely, anomalies of growth and nutrition impressed upon the growing nerve cell as well as upon the neuroglia cell, and affecting predominantly this or that area of the brain, frequently in territories corresponding to a particular vascular distribution. In cases of epilepsy supervening in adult life, after the brain cells had attained complete development, the changes found were, as regards the nerve cells, only of the second kind. But in addition these very frequently exhibited intranuclear vacuolation of the cortical cells also. The significance of the changes especially associated with the epileptic neurosis (more particularly when occurring congenitally or in early life, and therefore entailing also a more or less obvious degree of mental impairment) is still more striking when it is remembered that in the brains of non-epileptic idiots and imbeciles similar lesions are generally absent, and the convolutionary forms may be, and often are, plump and well formed, though inclined to simplicity of arrangement. These are to be looked on as general arrests of development, not complicated of course with the epileptic neurosis. In the brains of non-epileptic imbeciles sclerosis and microgyria are both conspicuous by their absence. When the epileptic neurosis is present, however, this process also is present, and the other changes detailed are also present in varying degrees. It is in the combination of these two classes of pathologic changes that lesions are to be found, the surest indication, the seal as it were, of epileptic idiocy or epileptic imbecility in the brain.

Right of Appeal from Medical Board.—Does the Montana statute allow an appeal to an applicant who has been refused a certificate by the medical board authorizing him to practice medicine and surgery in the State on the ground that the applicant's examination papers show that he has not the requisite learning to entitle him to such certificate? This question was raised in the case of State v. District Court, and was passed upon by the supreme court of Montana. Its decision is of increased importance because a number of other States have similar statutes, and this appears to be the first authoritative adjudication of the question. The language especially involved is as follows: "In all cases of the refusal or revocation of a certificate to practice medicine by the said board, the person aggrieved thereby may appeal from the decision of the board to the district court of the county in which such revocation or refusal was made." It was argued by the attorney-general, that this provision only gave the right of appeal where the certificate was refused or revoked by the board for unprofessional, dishonorable, or immoral conduct, and that there was no appeal from the refusal of the board to issue a certificate on the ground of incompetency of the applicant. But, in examining the statute, the supreme court said it found no language that restricted the right of appeal to any particular class of cases. The terms of the statute are general, giving the right of appeal "in all cases of the refusal or revocation of a certificate to practice medicine by the said board." So it holds that it gives the right of appeal in the class of cases referred to in the question. Nay more, it holds that the trial in the district court, awkward, difficult, and unsatisfactory as same might be, would have to be *de novo*. Whether or not such laws are wise or unwise, politic or impolitic, it says is for the legislature to determine. Justice Hunt adds, in a concurring opinion, that judges often have to pass upon equally difficult questions, involving study and knowledge of abstruse sciences, and when these difficult problems arise they are permitted to call to their aid those who are most proficient and experienced in the branches of knowledge required to settle them. Nor does he think that courts will be disposed to reverse medical boards, if they can help doing it, where there is no wilful wrong or prejudice proved.

Societies.

The following sessions are noted:

Illinois.—Peoria City Medical Society, August 3.

Iowa.—Bussey District Medical Society, Tracy, July 29. Jasper County Medical Society, Newton, July 20.

Kansas.—Eastern Kansas Medical Society, Leavenworth, July 20.

Kentucky.—Henderson Medical Society, Henderson, July 28.

Maryland.—Baltimore County Medical Association, Towson, July 15,

Massachusetts.—Hampden District Medical Association, Springfield, July 20.

New York.—Northern District Branch of New York State Medical Association, Utica, July 20. Oneida County Medical Society, Utica, July 13.

Ohio.—Lorain County Medical Society, Lorain, July 20. Northeastern Ohio Medical Association, Steubenville, July 13. Northern Ohio District Medical Society, Sandusky, July 29. Union Medical Association, Lisbon, August 12.

Pennsylvania.—Tri-State Medical Association of Western Maryland, Western Pennsylvania and West Virginia, Bedford, Pa., July 15. Westmoreland County Medical Society, West Newton, July 15.

Rhode Island.—Newport Medical Society, July 21.

Vermont.—Union Medical Society, Manchester, July 20.

Wisconsin.—Fox River Valley Medical Association, Marinette, July 27. Inter-county Medical Society, Ashland, July 13. Inter-urban Academy of Medicine, Superior, July 16. Northwestern Medical Association, Stevens Point, July 11.

Ontario, Canada.—Lambton Medical Association, Lambton, July 21.

Louisville.

Dr. William Bailey, ex-president of the American Public Health Association, has received a notification from Hon. Gardner G. Hubbard, chief of the Committee on Awards of the Tennessee Centennial Exposition, of his appointment by Dr.

Geo. M. Sternberg, chairman of the Committee on Awards for the Department of Hygiene, as a member of that Committee. The Committee will convene at Nashville October 8, and will probably be in session about one week.

PENSION EXAMINERS.—The appointment of the Republican members of this Board has recently been announced as follows: Drs. William Bailey, Allen Kelch, J. Hunter Peake. It seems that under a recent ruling the members of the Board appointed by a Democratic President can not be removed as they are protected by the Civil Service, but the appointment of the three republican members will divide the work among six instead of three as formerly.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.—Arrangements are being rapidly completed for the entertainment of the visiting members and friends of this Association, and from the present outlook there will be a large attendance and a full program. One of the features of the meeting will be a souvenir button provided by the local committee, which will contain an engraved likeness of Ephraim McDowell, which will be appreciated by all those receiving them. Louisville is justly proud of her reputation for hospitality and every endeavor will be made to live up to it.

BRITISH MEDICAL ASSOCIATION.—Dr. J. B. Marvin, ex-president of the Kentucky State Medical Society, was at the last meeting of that Society appointed a delegate to represent the Society at the next meeting of the British Medical Association at Montreal. Dr. Henry E. Tuley has also received an invitation from the Montreal branch of the British Medical Association and will attend.

Washington.

ANNUAL REPORT OF THE CORONER.—The Commissioners have received the report of Coroner Hammett for the year ending June 30, 1897, which shows as follows: The number of deaths during the year were 581 and are divided as follows: Accidental deaths, 100; suicide, 33; homicidal, 12; violent deaths, 145; deaths from natural causes, 328; still births, 108. There were 43 autopsies and 34 inquests held during the year.

NEW INSPECTORS APPOINTED.—The Commissioners have appointed Drs. Walter D. Cannon and Edwin L. D. Roach sanitary and food inspectors for the District.

DRUG INSPECTOR RECOMMENDED.—The annual report of the Commissioners of Pharmacy was submitted to the Commissioners July 31. It shows during the year a total of eight pharmacists registered upon examination and thirty-nine upon diploma. A recommendation is made in the report for an inspector of drugs as follows: The appointment of an inspector of drugs, who would have the right to go into the pharmacies of the city and condemn any medicine offered which does not measure up to the requirements of the United States Pharmacopeia, is earnestly recommended. Instances in faulty manufacture of preparations are cited.

DENTAL EXAMINERS' REPORT.—The annual report of the [illegible] of Dental Examiners has been submitted to the Commissioners. It shows that certificates entitling to registration have been issued to twenty two persons. The total number of dentists registered in the city is now 300.

THE PUBLIC SERVICES.

Army Changes. Official List of Changes in the Stations and duties of officers serving in the Medical Department, U. S. Army, from July 24 to 30, 1897.

Col. Dallas Bache, Asst. Surgeon-General, U. S. A. (Omaha, Neb.), is granted leave of absence for one month, with permission to apply for an extension of one month.

Capt. John L. Phillips, Asst. Surgeon, is granted leave of absence for four months, to take effect upon the arrival of Capt. Frank R. Keefer, Asst. Surgeon, at Ft. Walla Walla, Washington.

Navy Changes. Changes in the Medical Corps of the U. S. Navy for the two weeks ending July 24. 1897.

Surgeon C. G. Herndon, ordered to special duty at naval rendezvous, Duluth, Minn., July 19.

Asst. Surgeon S. B. Palmer, detached from the "Texas" and ordered to the "Annapolis" July 20.

Asst. Surgeon F. L. Pleadwell, detached from the "Constellation" 17th inst., and ordered to the "Texas" July 20.

P. A. Surgeon G. B. Wilson, ordered to the "Constellation."
P. A. Surgeon L. W. Spratling, detached from naval hospital, Norfolk,
P. A. Surgeon L. W. Spratling, detached from naval hospital, Philadelphia, July 19,
and ordered to naval hospital, Philadelphia, July 19.
P. A. Surgeon R. M. Kennedy, detached from naval hospital, Philadel-
phia, July 19, and ordered to naval hospital, Norfolk.
Asst. Surgeon J. C. Pryor, detached from naval laboratory, New York,
and ordered to the naval hospital, Mare Island, Cal.
Asst. Surgeon W. M. Wheeler, detached from naval hospital, Mare Island,
and ordered to the "Oregon."

Asst. Surgeon A. Farenholt, detached from the "Oregon" with insane patient to Washington, then to the "Vermont."

Asst. Surgeon C. E. Riggs, detached from the "Vermont" and ordered to the New-York navy yard.

Medical Inspector A. F. Price, detached from the New York navy yard July 14 and ordered to the "Olympia" as fleet surgeon.

Medical Inspector J. A. Hawke, ordered to the New York navy yard August 14.

Medical Inspector J. G. Ayers, detached from the "Olympia" as fleet surgeon, ordered home and granted two months' leave.

Surgeon H. E. Ames, detached from the "Cincinnati" July 25, and ordered to the naval hospital, Yokohama, per steamer August 14.

Surgeon J. C. Byrnes, detached from the Norfolk navy yard and ordered to the "Cincinnati" July 25.

Surgeon P. Fitzsimons, detached from naval hospital, Yokohama, on relief, ordered home and placed on waiting orders.

CHANGE OF ADDRESS.

Bowers, W. C., from La Place to Rooms 210-212 Milliken Blk., Decatur, Ill.; Bushang, L. B., from Maple Hill to Lyndon, Kan.; Bosworth, F. H., from 26 W. 46th Street, to 41 Park Avenue, New York, N. Y.

Curts, F. G., from Peoria to 208 Genesee Street, Waukegan, Ill.; Cheshire, M. U., from Anamosa to Cascade, Iowa; Crawford, S. K., from Baltimore, Md., to 440 Hermitage Avenue, Chicago, Ill; Carter, R. H., from Belton, Texas to Lynnville, Tenn.; Campbell, R. A., from Bellingham to 267 Cedar Avenue, Minneapolis, Minn.; Carpenter, Julia W., from Cincinnati Ohio, to Bay View, Mich. (Temporary address).

Givens, J. W., from Los Angeles, Cal., to Blackfoot, Idaho.

Hartman, F. T., from Anamosa, Iowa, to Victoria, Texas; Hatch, W., Grant, from Schleisingerville, Wis., to 357 S. Lincoln Street, Chicago, Ill.; Heise, W. F. C., from 215 S. Winchester Avenue to Presbyterian Hospital, Chicago, Ill.; Hakanson A., from 198 92d Street to 7716 Coles Avenue, Chicago, Ill.

Lehon, J. W., from Dunlap to Aurora, Ill.

Ohlmacher, A. P., from Cleveland to Gallipolis, Ohio.

Rohr, S. M., from Geyserville ro Santa Rosa, Cal.; Rucker, H. N., from 524 13th Street to 668 14th Street, Oakland, Cal.

PRINCIPLES UNDERLYING THE SERUM DIAGNOSIS OF TYPHOID FEVER AND THE METHODS OF ITS APPLICATION.

Presented in Opening the Discussion on Serum Diagnosis in the Section on Practice of Medicine, at the Forty-eighth Annual Meeting of the American Medical Association, at Philadelphia, Pa., June 1-4, 1897.

BY WILLIAM H. WELCH, M.D.
PROFESSOR OF PATHOLOGY, JOHNS HOPKINS UNIVERSITY.
BALTIMORE, MD.

I comply the more readily with the suggestion of the Chairman of this Section that my remarks in opening this discussion on the "Serum Diagnosis of Typhoid Fever," shall relate to the general principles of the method, inasmuch as the results obtained by this method at the Johns Hopkins Hospital will be presented in the course of this discussion by Dr. Block, and others will relate the results of their personal experience.

Before the introduction of the Widal method of diagnosis the discovery and subsequent studies of the typhoid bacillus had been comparatively barren of results available to the general practitioner of medicine. In this respect the typhoid bacillus afforded a marked contrast to many other pathogenic microorganisms, notably the tubercle bacillus, the diphtheria bacillus and the malarial parasite.

For various reasons improved methods of diagnosis of typhoid fever are most welcome to the practitioner. Inasmuch as the prevalence of this disease is a just reproach to the sanitary conditions of a locality, there has often been a readily explicable, if not creditable, reluctance on the part of some physicians, especially in public institutions, country towns and summer resorts, to make the diagnosis of typhoid fever even in clear cases. Moreover, notwithstanding all that has been written on the subject, knowledge of the frequent deviations of typhoid fever from the classical type, amounting sometimes to entire absence of all features of this type, can hardly be said to have become sufficiently common property of the medical profession in this country. The differential diagnosis of typhoid fever from certain other diseases, such as acute miliary tuberculosis, tuberculous peritonitis and meningitis, acute ulcerative endocarditis and various other septic affections, may, for a time at least, be most difficult or impossible, even to skilled diagnosticians. In children the disease is prone to anomalous manifestations. Since the discovery of the malarial parasite there is no longer any excuse for confounding typhoid and malarial fevers. A method of positive diagnosis of typhoid fever will elucidate the much disputed nature of many short and mild febrile diseases and of certain fevers of warm climates, as in the southern part of this country.

Before the introduction of serum diagnosis, numerous attempts had been made to utilize the presence of the typhoid bacillus for purpose of diagnosis. One can obtain with considerable regularity cultures of the typhoid bacillus by hypodermic puncture of the spleen in typhoid patients; but this procedure is not wholly without danger. Anyone who has seen at autopsy a swollen, soft typhoid spleen with its capsule distended to the utmost and ready to burst the moment it is lifted from the body, would certainly hesitate to insert even a hypodermic needle into such a spleen during life. Instances are on record in which such puncture of the spleen has given rise to severe intraperitoneal hemorrhage. Cultures from roseola spots, suggested by Neuhauss in 1886, yield uncertain results. Cultures from the blood give positive results in some cases, especially if large amounts be used. Cultures from typhoid stools reveal the presence of the specific bacillus in many cases if the examination be made with sufficient patience and care. The introduction of the Elsner and of the Capaldi nutritive media marks a distinct advance in this method. None of these procedures, however, in their present form afford simple and ready methods of diagnosis in the routine of hospital and private practice.

History.—The Widal method of diagnosis is based on the application of scientific discoveries made before Widal's first publication, June 26, 1896. As a controversy for priority, attended with no little bitterness, has arisen, it may be well to state the main historic facts. Like so many other bacteriologic discoveries of practical utility, this one is the outcome of investigations concerning immunity.

In 1889, Charrin and Roger noticed that the bacillus pyocyaneus grows in the form of clumps in the undiluted serum of animals rendered immune from this bacillus, whereas in normal serum it grows with diffuse clouding of the medium. This is the first observation of the property of immune serum to cause agglomeration of specific bacteria.

In 1891, Metchnikoff observed the same phenomenon together with immobilization of the bacteria in cultures of the vibrio Metchnikovi, and also clumping of the pneumococcus, in their immune sera and he said: "This fact, presenting a general importance, should be investigated more fully." He did not, however, pursue the investigation, and as he failed to find the same behavior of the hog cholera bacillus[1] in its immune serum, he seems to have abandoned the idea first expressed as to the general importance of the phenomenon.

In 1893, Issaeff, in the Pasteur Institute, and in 1895, Washbourn, confirmed Metchnikoff's observation as to the pneumococcus, and in 1894 Issaeff and Ivanoff, in Koch's Institute, made the same observation regarding the vibrio of Ivanoff.

In 1894, Pfeiffer, in conjunction with Issaeff, published his important studies on immunity from Asiatic cholera, in which he showed that cholera spirilla introduced into the peritoneal cavity of immunized guinea pigs, or introduced together with immune serum into the peritoneal cavity of normal guinea pigs, quickly lose their motility and break up into small granules. This behavior in the animal body, known as the

---

[1] As a matter of fact, the hog-cholera bacillus is agglutinated and immobilized by immune hog cholera serum, as has been shown by Dawson (New York Med. Journal, Feb 20, 1897). This is an additional proof, if any were needed, of the fact repeatedly insisted upon by the writer and others in this country, that Metchnikoff's so called hog cholera bacillus is not the genuine hog cholera bacillus discovered and described by Theobald Smith (Welch and Clement. Proceedings of the 30th Annual Convention of the U. S. Veter. Med. Assoc and 1st Veterinary Congress of America, October, 1893).

"Pfeiffer phenomenon," and demonstrated in 1896 by Pfeiffer and Kolle also for typhoid infection, became the subject of investigation by others, which led to the recognition of the importance and general bearings of the agglutinative reaction of specific sera. The Pfeiffer phenomenon is distinct from the agglutinative reaction upon which the method of serum diagnosis to be here considered is based, and Pfeiffer himself can not be credited with a clear recognition of the diagnostic importance of the latter reaction before it was made manifest by the work of others. He, however, directed attention to the diagnostic employment of serum with his reaction, and his discoveries formed the basis for the later work on the agglutinative reaction and, therefore, they occupy an important position in the history of serum diagnosis.

In 1895, Bordet, in studying the conditions of production of the Pfeiffer phenomenon outside of the animal body, noted that if a small quantity of immune serum be added to a suspension in salt solution or bouillon of cholera spirilla these lose their motility and become agglomerated. The significance of Bordet's observation is that he was the first to dilute the serum. His interest, however, was chiefly in the determination of the conditions causing the disintegration of the spirilla by cholera serum, and it can not be said that, at this time, Bordet had a clear perception of the importance and general significance of the agglutinative reaction.

January 3, 1896, Durham presented to the Royal Society a paper giving the results of investigations in Gruber's laboratory in Vienna. This communication embodies the first thorough and systematic study of the agglutinative and immobilizing properties of immune serum outside of the animal body. In this and the rapidly following papers of Gruber and Durham the real importance and general characters of this reaction with immune serum were for the first time made clear. The macroscopic and the microscopic tests, the importance of dilutions, quantitative estimations of agglutinative power, the value of the test for the differentiation of bacterial species and for the determination of a previous attack of cholera or typhoid fever, and many other details were described.

It seems but a small step to determine whether a reaction which had been demonstrated to characterize the serum of animals and human beings which have recovered from an infection may not also be present during the period of infection, but upon this step depended the applicability of the reaction as a method of clinical diagnosis. It was Widal who took it and thereby made available for the diagnosis of an infection a reaction which had previously been thoroughly worked out by Gruber and his collaborators so far as immune serum is concerned.[2] Widal's first communication was presented to the Société Médicale des Hôpitaux on June 26, 1896. This first paper has been followed by numerous important contributions by Widal and others to the same subject.[3]

Nature of the agglutinative property and reaction.—As the result of infection with many bacteria or of intoxication with their products, the blood, even when highly diluted, acquires the property of causing loss of motility and clumping together of the specific bacteria concerned in the infection or intoxication. The clumping is called by Gruber agglutination, and is attributed by him to the presence of substances to which he has given the name agglutinins. He supposes that these agglutinins make the gelatinous capsules of the bacteria swell up and thereby stick the bacteria together. Although there is no proof of this theory, the names "agglutination," to designate the phenomenon, and "agglutinins," for the supposed substances causing it, have been widely adopted.

In the case of motile living bacteria two phenomena characterize the complete reaction, paralysis or immobilization of the bacteria and clumping. Usually these two phenomena go hand in hand, but sometimes there is loss of motility with little clumping or clumping without much cessation of motion, so that the opinion has been expressed that the paralyzing and the agglutinative substances are not identical. The more common deviation from the usual course of the reaction is the occurrence of clumping, with partial preservation of motility.

The agglutinative serum reaction appears to be of wide, although not universal, application, both for motile and non-motile pathogenic bacteria, having been demonstrated for typhoid, Asiatic cholera, pneumococcus infection, tetanus, pyocyaneus disease, glanders, hog-cholera, Malta fever, colon infection, proteus infection, psittacosis, and several other infections.

The change in the blood upon which the reaction depends is doubtless a specific one in the same sense as are the antitoxic, lysogenic, and other specific alterations caused by the action of definite bacteria or their products. It is upon this specificity that the diagnostic value of the reaction is based. It is true that, as in the case of the antitoxic, lysogenic and other protective modifications of the fluids of the body, the normal blood may possess in some degree the same property, so that the specific character of the change may not be apparent without resorting to considerable dilution of the blood or serum. Normal blood may agglutinate, to some degree, not only the typhoid bacillus but various other bacteria. The specificity of this change resulting from infection with a given microörganism is made apparent by increase of the agglutinative power of the serum only for that microörganism, or to some extent also for closely allied microörganisms. The increase of reaction in some degree with closely allied bacteria, does not militate against the specificity of the change, for it is only an expression of the natural affinities between varieties and races of organisms, as between the typhoid bacillus and the bacillus of psittacosis, or between the cholera spirillum and certain other spirilla, or between the varieties of proteus bacilli or of colon bacilli. The development of the specific agglutinative properties of the blood in typhoid fever affords additional proof, if any were needed, that the bacillus typhosus is the specific cause of this disease.

The blood acquires the specific agglutinative power at a variable period, usually within a few days, after the entrance of the pathogenic microörganism or its products. This power tends to increase, but with much irregularity, during the course of the infection, and gradually to diminish and finally to disappear weeks, months, or it may be years after recovery from the infection. Widal lays much emphasis on the reaction being one of infection and not of immunity. Still it is to be noted that by following procedures for raising experimental immunity to great heights, there may be a corresponding rise of agglutinative power, whereby degrees of this power may be attained which are entirely unknown during natural infections. Thus, Widal, by successive inoculations of an ass, has secured typhoid serum with an agglutinative strength of 1 to 43,000, and Salimbeni has obtained, experimentally, cholera serum agglutinating in a dilution of 1 to 50,000. Gruber speaks even of immune sera which agglutinated distinctly in a dilution of 1 to 500,000. There is, however, no necessary correspondence between the height of immunity and that of agglutination; especially may the latter lessen or disappear when the former is preserved. In the light of the experimental results, and for other reasons, it seems to me somewhat misleading to designate the reaction as merely one of the period of infection.

We are not informed as to the nature of the relationship between the agglutinative and the protective properties of the blood. Gruber has based a new theory of immunity on the agglutinative reaction, but this theory is opposed by many facts and can not be accepted. The agglutinative property has been shown to be distinct from the bactericidal, lysogenic, antitoxic and other known protective properties of the blood. At present we have no satisfactory evidence that the agglutinative reaction is concerned in any of the defensive mechanisms of the body. According to Salimbeni, whose results, however, are not in entire accord with those of Durham, agglutination of bacteria does not take place within the animal body, although it has been demonstrated that the living blood plasma possesses the agglutinative property.

---

[2] It appears that Grünebaum, working in Gruber's laboratory, had determined the agglutinative property of the blood serum during the period of typhoid infection before Widal's first publication, but the results of his investigations were not published until after several papers by Widal and others had appeared.

[3] A summary of their own work on serum diagnosis, as well as that of others, with references to literature, is presented in a recent elaborate paper by Widal and Sicard in the Annales de l'Institut Pasteur, 1897, No. 5.

We do not know the origin or nature of the so-called specific agglutinating substance, save that in some way it results from the activities of bacteria or their products within the living body. Gruber believes that it is derived from the bodies of the bacteria through the agency of the cells. Bordet considers that it is secreted by leucocytes. Experiments of Widal and Sicard, and of Achard and Bensaude, indicate that it is not secreted by leucocytes outside of the living body, but there is nothing which shows that it may not be formed by cells within the body.

The agglutinative substance is generally believed to be a proteid, as it is precipitated from blood plasma with fibrinogen and globulin, and from milk with lacto-globulin and casin, but it is possible that it is simply mechanically retained by these albuminous precipitates. In typhoid fever it may be absent from albuminous urine and may be present in urine which gives no reaction for albumin (Widal). It behaves like an albuminous substance as regards filtration and dialysis.

The question whether it is strictly proper to speak of agglutinative, bacterolytic, antitoxic, substances in the blood is a legitimate one. They have never been isolated as chemical substances. Behring has expressed the opinion that isolation of antitoxin will never be accomplished, for, in his opinion, it is a force pertaining to highly organized material, and there is no more possibility of separating it as a substance than of isolating the magnetic force from an iron magnet. In all probability these various properties, agglutinative, bacteriolytic, antitoxic, belong to the same general category, and we may look upon the agglutinative property also as a physical one which proteid substance may acquire as the result of the activities of bacteria or their products, and no more separable in the form of a chemical substance than is electricity.

The agglutinative property is quite resistant to injurious agencies. It survives desiccation of the blood or serum for months, and may persist for months in blood serum, even when this is seriously contaminated with microorganisms. It is not destroyed by sunlight, unless overheated. It is weakened by prolonged heating at 60 degrees C., and is annulled by heating for ten minutes at 75 to 80 degrees C.

The agglutinative property in typhoid fever is present in maximum amount in the blood, being somewhat greater in the blood plasma than in the blood serum. It is found in blister serum in essentially the same strength as in blood serum. In other fluids, as the pleural, peritoneal, pericardial, inflammatory and edematous, it is in smaller and variable amount. In milk and colostrum it is present in marked degree. It is weak and inconstant in the urine, bile and aqueous humor. It has been found in tears naturally secreted, but is said to be absent from those provoked by irritants. It may be present in typhoid stools (Block). It has not been found in the cerebrospinal fluid or the fluid in the seminal vesicles. It has not been positively determined whether the distribution of the agglutinative property in the various humors of the body outside of the blood, can be explained wholly by processes of filtration and diffusion from the blood plasma, although these are doubtless the main factors.

The agglutinative reaction may or may not be obtained with the blood of a fetus or new-born infant of a mother with typhoid fever. Chambrelent and Saint-Philippe consider that the presence or absence of the reaction in the fetus depends on whether or not the typhoid bacilli break through the placental barrier from mother to fetus and cause infection of the latter. Further investigations are needed to determine this point and thus to decide whether the agglutinative property is passively or actively acquired by the fetus. For it has been shown that this property, like immunity, not only may be actively acquired as the result of infection or intoxication, but may be passively transmitted by injection of agglutinative serum, the reaction in the latter case appearing promptly without symptoms of infection. being relatively slight, and disappearing after a short time.

Courmont thinks that the development of typhoid bacilli in a fluid robs it of agglutinative power. Thus he has found that the vegetation of the bacilli in typhoid serum deprives it, in a few days, of the agglutinative property, and that blood obtained, post-mortem, from the spleen, liver and mesenteric glands, organs in which the typhoid bacilli are especially abundant, is poorer in agglutinative power than that from other parts. Ménétrier found in a case of typhoid fever that the pleural exudate, which usually gives the agglutinative reaction, did not do so, and that it contained typhoid bacilli in large number. It has been suggested that these observations may shed light on the exceptional cases of typhoid fever with absence of the specific serum reaction. Flexner has shown that, occasionally, the typhoid bacilli develop in the blood in such large numbers as to produce a genuine typhoid septicemia. Still these observations, interesting as they are and deserving further investigation, must be interpreted with caution, for Widal has found a purulent exudate from an immunized ass, swarming with typhoid bacilli, to present, even after fifteen months' preservation, an agglutinative power of 1 to 13,000, the power of the blood serum of the same animal kept for the same length of time being 1 to 14,000.

We have no satisfactory explanation of the production of the phenomenon of agglutination by specific serum. Gruber's explanation already mentioned has received no confirmation. The phenomenon occurs with non-motile as well as with motile bacteria, with dead as well as with living organisms. Typhoid bacilli killed by formol in weak solution, or by heating for five minutes at a temperature of 56 degrees C., are about as sensitive to the reaction as are living bacteria, and retain their agglutinability for a long period (Widal). The phenomenon, therefore, is a physical rather than a vital one, although probably dependent in some way on the protoplasmic constitution of the bacterial cell. Salimbeni, as has been stated, found that the phenomenon does not occur in the living body of immunized animals. He also found that the presence of atmospheric air greatly favors the reaction, it requiring much more concentrated serum and a longer time to bring about the phenomenon in a vacuum than when the fluid is exposed to the air. Widal has shown that other physical conditions, particularly contact with objects, such as the surface of slide or cover-glass, and partial evaporation, favor the production of the reaction.

Agglutinative serum is often likewise bactericidal and bacteriolytic, but the agglutinative reaction is independent of the bactericidal and is manifest with dilutions of the serum which annul the bactericidal power. In such dilutions the agglutinated and immobilized bacteria are not altered morphologically, or in staining properties, or in pathogenic power, or in any other way, so far as has been determined. Whether the temporary inhibition of bacterial growth in agglutinative serum is dependent on the agglutinative or on some other property of the serum is not known.

Methods of making the serum test for typhoid fever.—Widal, in his first communication, described both the slow or macroscopic and the quick or microscopic methods. For each of these he recommended a dilution of one part of blood or blood serum to ten parts of the fluid containing the culture. The macroscopic method consists in adding the blood or serum to be tested either to a young bouillon culture of the typhoid bacillus or to sterile bouillon which is then at once inoculated with the bacillus. In the former case the reaction with typhoid serum appears usually within two or three hours and consists in clarification of the previously turbid fluid, and the formation of a clumpy sediment composed of accumulated bacilli. In the latter case the tube is placed in the incubator and within fifteen hours the reaction is manifested by growth of the bacilli in the form of a sediment at the bottom of the tube, the fluid remaining nearly or quite clear.

The microscopic test, to which Widal gave the preference, is made by mixing the blood or serum with a young bouillon culture or with a suspension in bouillon or salt solution of a fresh growth of the typhoid bacillus and examining a drop or two of the mixture at once under the microscope. With a dilution of 1 to 10 this microscopic typhoid reaction appears, as a rule, immediately or within a few minutes, and is evidenced by loss of motility and by clumping of the bacilli into masses of various sizes and shapes.

Widal obtained the blood either with a sterilized hypodermic syringe from a vein of the arm, or by pricking the finger. It may also be conveniently obtained by pricking the lobule of the ear. A few drops of blood suffice for collecting the necessary amount of serum; indeed a single drop will do for the reaction. The blood may be collected in a small test tube where, usually in a few minutes, it clots. The separation of the serum may be facilitated by passing a sterilized platinum needle between the glass and the clot, or by the centrifuge, or the blood may be collected and allowed to clot in a slanted tube, which is then placed upright, the separated serum trickling to the bottom.

In a communication made July 31, 1896, Widal said that results equaling those with blood serum can be obtained with blister serum, and this procedure has been employed with much satisfaction by the Health Department of New York city.

At the same time Widal called attention to the preservation of the agglutinative property in dried blood and serum. Wyatt Johnston deserves t credit of developing the test with dried blood and i introducing the method of serum diagnosis into t work of municipal laboratories. The dried-blo method, which has been used far more extensive in Canada and this country than in Europe, possess certain manifest advantages, especially ease of colle tion, freedom from subsequent contamination an readiness of transportation, and it has given excelle results in the hands of Johnston and others. Th principal objection, and this is of considerable impor ance when precise results are desired, is the difficul of obtaining accurate quantitative dilutions with th use of dried blood.

Several observers, including Breuer, Haedke, D Mesnil de Rochemont, Scheffer, have expressed th opinion that the macroscopic method is more trus worthy than the microscopic. This I believe to be a error and to be due to unfamiliarity with all of th conditions essential for the accurate employment o the *microscopic* test. The latter is more delicat prompt and precise than the macroscopic reactio and requires less care in respect to accidental contamination.

A year's experience with the method of serum diagnosis of typhoid fever has led to a general consensu of opinion as to its great value. It has, howeve been recognized that certain precautions in the application of the test are necessary in order to avoi mistakes. Numerous modifications of the origina methods have been suggested, the most importan relating to quantitative determinations. In considering the value and practical utility of such modifications of the test, several points should be borne i mind. Practically all of the methods recommende by competent investigators have given good results i the great majority of cases. For clinical purposes i is desirable that neither the method of obtaining an collecting the blood, nor that of conducting the tes should be made more difficult and complicated than i absolutely necessary. Methods which may be essential for exact scientific work, where every possibl source of fallacy is to be avoided, may not be the bes for the routine examinations of a clinical or a municipal laboratory. Where absolute accuracy is not obtainable it is upon the whole better that the method should err on the side of now and then including a non-typhoid case than in excluding cases of genuine typhoid fever. With due allowance for such considerations as these, we must welcome all efforts to give greater precision to the methods of serum diagnosis and to determine the capabilities of these methods and their possible sources of error. In exact quantitative work with the serum test the most important points to be considered are the characters of the culture, the dilution of the serum, the time limits, the criteria of the reaction and certain physical conditions influencing the reaction.

Characters of the culture.—There has been considerable difference of opinion as to whether cultures of the typhoid bacillus obtained from different sources are equally sensitive to the agglutinative reaction. Widal, Durham, Stern and C. Fraenkel, who have all had large experience with different cultures, have found only unimportant and inconstant differences in susceptibility to the reaction. The fact determined by Pfeiffer that the less virulent the culture, the greater the sensitiveness to the lysogenic reaction (Pfeiffer's phenomenon), seems to have been considered by many without sufficient investigation to be equally applicable to the agglutinative reaction. Kolle, without however presenting sufficient evidence, emphasizes the greater susceptibility of cultures with weakened virulence to agglutination. The most satisfactory evidence on this point is furnished by Kuhnau, who made a careful comparative study of the behavior with the serum test of a non-virulent and a virulent typhoid culture, and found the former to react much more intensely with normal and typhoid sera. He, therefore, lays stress on consideration of the virulence of the culture in quantitative work with the serum test. In view of the conflict of opinion further investigations upon this question are needed.

It cannot be doubted that several observers have had to do with typhoid cultures which presented distinct differences in susceptibility to the agglutinative reaction. Especially worthy of consideration, although not wholly in accordance with some results of others, are the observations of Johnston and McTaggart, confirmed by Appel and Thornbury, that solutions of dried blood are more potent than serum in agglutinative power, although not in paralytic effect, and that such solutions from non-typhoid cases are prone to give partial (pseudo-) reactions with frequently transplanted typhoid cultures, whereas this difficulty is largely overcome by using fresh cultures planted from stock cultures a month old. Hence they strongly recommend for the dried-blood method cultures of the latter character. They, as well as other writers, likewise emphasize the importance of considering the composition of the culture medium, which should be favorable to vigorous growth and not too strongly alkaline.

Only young cultures should be used, preferably not over twelve to eighteen hours old, if grown in the incubator. Older room cultures can be used. Old cultures agglutinate more readily than young ones. Either bouillon cultures or suspensions in bouillon from solid cultures may be employed. There is no difficulty in securing uniform suspensions of isolated, actively motile typhoid bacilli, especially from young cultures on dried-out agar. In every case it is of prime importance to make a control examination of a drop from the same part of the culture or suspension which is used for the test and at the time of making the test in order to be sure that there are no preexisting clumps, that the bacilli are actively motile, and that the culture is not contaminated.

Stern suggested that the concentration of the suspension, that is the number of bacilli in it, may be a factor meriting consideration, and Kuhnau and Block have shown that this is the case. Weak suspensions are more readily agglutinated and paralyzed than stronger ones. Hence, Kuhnau recommends the use of suspensions of known concentration, which can be approximately secured without much difficulty. He uses a suspension in bouillon of a fifteen-hour virulent agar culture (grown in the incubator) containing about one hundred and twenty million bacteria in a cubic centimeter.

Dilution of the serum.—Inasmuch as normal and non-typhoid blood may possess distinct agglutinative property, especial importance is attached to dilution of the serum, in order to avoid mistaking the normal reaction for one of typhoid fever. The opinion has been widely expressed that the dilution recommended by Widal, 1 to 10, is too low, and that a dilution should be used which is not known ever to give a reaction with non-typhoid blood. The fixation of the upper limit of such a dilution has been placed gradually higher and higher, thus by du Mesnil at 1 to 25, by Kolle 1 to 30, by Grunbaum 1 to 33, by Stern 1 to 40, by Kühnau 1 to 50. Even if it should be admitted that a reaction in non-typhoid cases with these higher dilutions is ever of such a character as might mislead an experienced observer, its occurrence is, according to most observers, very exceptional.

The question arises whether the adoption of a dilution of say 1 to 50 as the standard, would result in the exclusion of genuine typhoid cases from the diagnosis. Widal divides the typhoid cases in which he has measured the agglutinative power of the blood into five groups: *a*, those with very weak power, less than 1 to 100 (four cases); *b*, with weak power, between 1 to 100 and 1 to 200 (nine cases); *c*, with medium or average power, from 1 to 200 to 1 to 500 (eight cases); *d*, with high power, from 1 to 500 to 1 to 2,000 (nine cases); and *e*, with very intense power, exceeding 1 to 5,000 (three cases). In only one case did the agglutinative power not rise over 1 to 40, it being 1 to 30 on the twentieth, and 1 to 40 on the twenty-second day of the disease. In one case, Widal found the strength to be 1 to 12,000. In nineteen cases measured by Stern, the agglutinating strength was never less than 1 to 50. C. Fraenkel found the average to lie between 1 to 100 and 1 to 200, sometimes reaching 1 to 5,000. Out of seven cases Kuhnau found two in which the serum was active only in dilutions less than 1 to 50, it being 1 to 30 in one, and 1 to 20 in the other case, but in both he made a positive diagnosis of typhoid fever in consequence of disparity of the action of the serum on the colon bacillus and the typhoid bacillus. From the observations thus far reported, although they are insufficient in number for definite conclusions, there would seem to be only small liability of failure to recognize genuine typhoid cases by resorting to dilutions of 1 to 40 or 1 to 50, but unquestionably a few cases would escape recognition, and for this reason lower dilutions should also be used, and if those between 1 to 10 and 1 to 50 give decided reaction there should be, at least, suspicion of typhoid fever.

It is not, therefore, to be recommended that one should make the test with only high dilution, such as 1 to 50. The negative result of a preliminary test with equal parts serum and culture suffices to exclude typhoid reaction. The examination, if positive, may then be made with a low dilution of the serum and for this Widal's recommendation of 1 to 10 or 1 to 15 may be well adopted. If with this dilution the microscopic reaction is complete and almost immediate, as is often the case, there is practically no risk in making a positive diagnosis. But for absolute certainty and above all in cases where the result of the reaction is not prompt, complete and unmistakable, higher dilutions should be employed; if the amount of serum permits only one such, it may be 1 to 50, but preferably intermediate dilutions should also be made, and it is desirable, if not absolutely necessary, to try dilutions higher than 1 to 50. For making the dilutions there are various simple technical procedures, which involve but little expenditure of time and labor and only small quantities of serum, as, for example, that recommended by C. Fraenkel. An accurate fixation of the upper limit of agglutinative power is often tedious and not generally necessary in diagnostic work. A positive diagnosis of typhoid fever, based exclusively on the test with a low dilution, in a case which subsequently proves not to be typhoid should not be considered as in any way invalidating the results of an accurate employment of the method of serum diagnosis.

It is self-evident that the employment of varying degrees of dilution of the serum, without at the same time taking into consideration other factors which influence the reaction, has little sense and does not constitute, in itself alone, an accurate method of mensuration of agglutinative power.

Time limits.—As the rapidity with which the reaction appears and progresses generally varies, other things being equal, according to the agglutinative strength of the blood it is evident that methods of exact mensuration of this strength must take into consideration the length of time required for the development of the reaction after the addition of the serum. Many writers have not paid much attention to this point. Stern has proposed that a limit of two hours be adopted as an arbitrary standard for the microscopic reaction, and Widal has accepted this proposal. With this unit, an agglutinative power fixed at 1 to 500 means that 1 part of serum added to 500 parts of the fluid containing the culture, agglutinates and paralyzes the bacilli within two hours, although a higher dilution may give a decided reaction in six or eight hours. The optimum effect is, according to Stern, not attained before the lapse of six or eight hours.

By varying the time limits, results obtained by lower dilutions may be roughly comparable with those by higher dilutions. Thus, for diagnostic purposes, a fifteen minute time limit for dilutions of 1 to 10 may be adopted and a two hour time limit for dilutions of 1 to 50 or higher, but it should be understood that in all doubtful cases quantitative determinations by varying the dilution should be employed.

Criteria of the reaction.—Some writers have proposed to make either the cessation of motility or the clumping the essential criterion of the reaction. Thus Stern selects the clumping and Kühnau the paralysis of motion. In my judgment both phenomena enter equally into the reaction and deserve equal consideration, so that a reaction is not to be considered complete and satisfactory unless the bacilli are both clumped and rendered immobile. Partial reactions in which one or the other characteristic is lacking may warrant suspicions and lead to further examination, but they should not be made the basis of positive diagnosis. For this reason the use of killed cultures, as suggested by Widal, while it may have a limited field of application, can not supplant the ordinary method. As already stated, the microscopic reaction is to be preferred to either of the macroscopic methods, although the latter afford striking objects for demonstration. With low dilutions bactericidal and lysogenic phenomena are common, but they do not pertain to the agglutinative reaction itself.

Certain physical conditions influencing the reaction.—As already mentioned Salimbeni has shown that free exposure to the air favors the reaction and Widal has pointed out that partial evaporation at the edge of the cover-glass and contact of the specimen with slide and cover-glass are also favoring conditions. Hence, the conditions for the reaction are not exactly the same with the serum bouillon mixture in thin layer beneath the cover-glass on an ordinary slide, as in a thick layer, or in a sealed drop culture on a hollow slide, or in a column of fluid in a test-tube, or in a moist chamber. The presence of fibrinous masses, granules and material foreign to blood serum may perhaps explain in part the greater frequency of partial reactions with normal blood when the dried blood method is used than when the serum method is employed. The temperature of the incubator, by favoring evaporation and in other ways, accelerates the reaction. For exact quantitative work these various physical conditions need consideration and further investigation. Widal prefers the use of ordinary slides to that of hollow-ground slides, and does not advise keeping the specimen in the incubator. It is not to be supposed that the diagnostic use of the serum test generally hinges on such delicate points as these, but they are among the points to be considered in the explanation of certain irregularities in the results of the test, in comparing the results of different workers, and in mensuration of agglutinative power, especially with high dilutions.

Reactions with the colon bacillus.—Statements of different writers as to the occurrence of the agglutination of the colon bacillus with normal and typhoid sera are not harmonious. Widal and Courmont find that all human sera, whether normal or typhoid, have a slight agglutinating action on the colon bacillus in dilution of 1 to 10, whereas normal sera have only exceptionally any such action on the typhoid bacillus in this dilution. Many observers have noted some agglutination of colon bacilli with typhoid serum, although the reaction is much less intense than with the typhoid bacillus. Vedel found, in a case with symptoms of typhoid fever but without the typhoid serum reaction, marked colon reaction, and he interpreted the case as one of colon infection simulating typhoid. He is not, however, inclined to attach much diagnostic importance to the colon reaction, as he found that it might be well marked both with normal and typhoid blood. Johnston and McTaggart found genuine colon reactions with typhoid blood to be rare, provided the typhoid reaction was well marked. In several cases, however, where the symptoms suggested typhoid but the typhoid serum reaction was absent, they found marked colon reaction. They are inclined, therefore, to attach diagnostic importance to the latter reaction. The colon cases were mild and of shorter duration than ordinary typhoid fever.

Kühnau makes use of the colon reaction to assist in the diagnosis of typhoid fever in doubtful cases. He finds that normal serum reacts in the same way with both colon and typhoid bacilli, whereas typhoid serum, even when of weak specific power, reacts much more intensely with the typhoid bacillus than with the colon bacillus. By availing himself of this unequal action of typhoid serum upon the two species of

with lesions of the intestine. It can very frequently be found in internal organs outside of the intestine in typhoid fever, if careful search is made. We have no satisfactory proof that it produces either symptoms or lesions in most of these cases, and one would expect more common and intense serum reactions with bacillus coli in typhoid fever, if the organism was engaged in pathogenic work. The writer has repeatedly taken occasion to protest against what seem to him unwarranted inferences as to the pathogenic significance of the mere detection of the colon bacillus in the internal organs at autopsies, although there can be no question that under certain conditions this bacillus may be pathogenic for man.

As the colon group of bacilli contains numerous races, some approaching the typhoid bacillus closely, it is to be expected that they will vary markedly in their sensitiveness to agglutination with different sera.

Durham found that typhoid immune serum in no instance produced any agglutinative reaction with ten different specimens of the bacillus coli obtained from various sources. Colon immune serum reacted on its own race of bacilli exactly like typhoid serum on typhoid bacilli, but it did not react with all races of colon bacilli, a graduated series of effects being observed with different specimens of these bacilli. Rodet, however, whose results are reported in much less detail than those of Durham, found a certain degree of reciprocal action between colon and typhoid immune sera and their respective bacteria.

Date of appearance and disappearance of the typhoid serum reaction. Absence of reaction.—The presence of the specific agglutinative reaction can usually be counted on by the end of the first or the beginning of the second week of typhoid fever. It may appear as early as the second day of the disease (Johnston and McTaggart, C. Fraenkel), but this is very exceptional. It may here be noted that the determination of the exact day of a disease, often so gradual and insidious in its development as typhoid fever, must frequently be more or less arbitrary, and will vary according to the case and with different observers. Sometimes the first appearance of the reaction is delayed, exceptionally until the end of the second or into the third week, or even later. There are rare cases in which the reaction is missed during the first attack and makes its appearance in the relapse (Breüer, Thoinot, Biggs and Park, and others). It has even been missed until the first days of convalescence. Blumenthal relates an interesting case in which the reaction was absent during the fever, tests being made on the twelfth and twenty-first days with serum dilutions of 1 to 10, but it was found with dilutions of 1 to 100 two days after the beginning of apyrexia. Achard likewise once found the reaction only during convalescence. We have not at present a sufficient number of accurate data to furnish definite figures as to the frequency of these delayed reactions, but their occurrence undoubtedly constitutes a defect in the method of serum diagnosis of some importance. A negative result of the test does not exclude the diagnosis of typhoid fever. The probability against this diagnosis is the greater, the later the period of the fever in which the negative result is obtained and the oftener the examinations are repeated. As regards the interpretation of negative reactions, the serum test does not differ from other bacteriologic diagnostic tests, that for the tubercle bacillus for instance.

There are authentic cases of typhoid fever in which repeated examinations of the blood during the course of the disease and its convalescence failed to reveal the specific agglutinative reaction, even with serum dilutions of 1 to 10. We can not at present say what percentage of the total number they make. Widal and Sicard found absence of the reaction in only one out of 163 cases of typhoid fever examined by them. In this negative case, in which the diagnosis was confirmed by cultivation of typhoid bacilli obtained by hypodermic puncture of the spleen, the reaction was absent during the fever, the apyrexia, the relapse and the convalescence. Of 116 cases of typhoid fever examined by Courmont, the reaction appeared in all, being delayed after the eighth day in only five. Of 70 cases examined by Chantemesse, it was present in all. Of 129 cases examined by Johnston and McTaggart, if a few cases examined only late in convalescence, or at a very early stage without reëxamination, be excluded, the reaction was missed in only one. In many reports cases, believed to be typhoid, are recorded as giving negative reaction when only one examination was made, this being sometimes early in the disease. Such cases doubtless belong mainly to the group with delayed reaction. The importance of repeated examinations is illustrated by such observations as Stern's, in which the test was negative at the end of the second week and positive two days later; of Widal's, negative on the tenth, positive on the twenty-second day, and several others of similar purport.

The agglutinative power of the blood tends to increase during the progress of the fever, but there are exceptions, and in general the intensity of the reaction is subject to irregularities and oscillations, which may be notable from day to day. There may be marked sudden rise or fall of reactive power. While weak reactions are more common in mild cases, there is no definite correlation between premature or delayed development or the intensity of the reaction and the gravity of the disease. The persistence of high agglutinative power, for example 1 to 2,000, after subsidence of the fever, does not prevent relapses.

In the majority of cases the specific agglutinative power of the blood diminishes in the first weeks or months after cessation of the fever and disappears within a year. Exceptionally it may vanish as early as eight or ten days after the fever. Widal and Sicard noted its disappearance on the eighteenth and twenty-fourth days, Breuer on the seventeenth and twenty-fifth days, E. Fraenkel on the twenty-eighth day after defervescence, etc. Disappearances at such early dates as these are, however, not the rule. According to Courmont's experience, the serum reaction disappears in children most frequently during the course of the first two months, and in adults toward the fifth and sixth months, although it is not uncommon for it to continue a year. The specific reaction may, however, persist for years, perhaps indefinitely. Of forty cases which had had typhoid fever at least a year before examination, Widal and Sicard found the agglutinative reaction, either marked or slight, in eleven; after one and one-half year, one case, reaction weak; after two years, one case, reaction weak; after three years, two cases, in one marked, in the other weak; after six years, one case, reaction 1 to 10; after seven years, one case, reaction marked; after eight years, one case, reaction 1 to 1,800; after nine years, three cases, one marked, one 1 to 40, one 1 to 30; after twenty-six years, one case, 1 to 30. Kühnau found after one year, two cases with reaction of 1 to 80; after two years, one case, reaction 1 to 60; after seven years, one case, reaction 1 to 60. All others of a series examined (total number not stated) showed negative reaction after one year. It was observed by Widal and Sicard that in contrast to the reactions during infection and for the first weeks after defervescence, those of long standing showed no notable fluctuations in intensity during the periods of examination, extending sometimes over several weeks.

The persistence of the specific reaction after typhoid fever is of importance from two points of view, retrospective diagnosis and interpretation of the diagnostic significance of the reaction during a febrile infection. It is sometimes of interest and practical importance to determine that an individual has previously had typhoid fever. Thus Courmont was able by the serum diagnosis to determine that a patient with multiple neuritis, supposed to follow an attack of dysentery, was in reality convalescent for a month and a half from typhoid fever, and Achard recognized the real nature of an attack of osteomyelitis in a patient who had had typhoid fever a year before (cited from Widal and Sicard)

Many writers have called attention to the evident possibility of a mistake in diagnosis when the serum reaction is found in a person with a febrile infection, who has recovered from typhoid fever, although it does not appear that any serious difficulty has been encountered thus far from this source of error. It, however, indicates the importance of obtaining a careful history of the patient, not only as regards recognized typhoid fever, but as to attacks interpreted as dysentery, gastric fever, appendicitis, malaria, etc. An observation reported by Stern indicates that the specific typhoid reaction may be acquired even without manifest illness. He suggests that careful quantitative estimations of agglutinative power may restrict the possibility of error in diagnosis arising from long persistent reactions, as increase or diminution in the course of the fever or of the convalescence would speak for fresh infection. Even if the fullest possible allowance be made for this source of error, it applies to so small a number of cases that the value of the method is not seriously impaired.

Presence of the reaction in non-typhoid cases.—The blood of many hundred persons, either healthy or affected with diseases other than typhoid, has been tested for the specific typhoid reaction, and it can now be asserted that a serum reaction which an experienced observer using accurate methods would consider characteristic of typhoid fever, is to be found only most exceptionally in those who have not had typhoid infection.

Several observers, especially the Germans, find that by adherence to Widal's original directions mistakes may occur, but that these can be avoided by attention to quantitative determinations, especially dilution of the serum, time limits, and characters of the culture used for the test. The most remarkable observations on this point come from Breslau and are reported by Stern and Kuhnau. Stern examined the blood serum of seventy persons not suffering from typhoid fever and, according to their statements, never having had typhoid fever. In twenty of these the serum had an agglutinative strength of 1 to 10, in five a strength of 1 to 20, and in two a trace of reaction was obtained with dilutions of 1 to 30. In none of these cases did he find any reaction with dilutions of 1 to 40. Of more than fifty similar cases examined by Kühnau, in forty-one no reaction was obtained with dilutions higher than 1 to 5. In eight agglutination was observed with dilutions of 1 to 10, up to 1 to 20; in four with 1 to 30; in three with 1 to 35, up to 1 to 40; and in one even with 1 to 50.

In judging these results, apparently so divergent from those of Widal and nearly all others, it is to be noted that both Stern and Kühnau used the microscopic reaction, made two hours the time limit, even for the lowest dilutions, kept the specimens in the thermostat, and that Stern regarded the clumping and Kühnau the paralysis of motion as the criterion of the reaction, thus apparently recording as genuine what many others would consider partial or pseudo-reactions. It is clear that those who interpret only complete reactions occurring within fifteen to thirty minutes at room temperature as genuine reactions, would not be likely to obtain any such results as those reported by Stern and Kuhnau. Nevertheless, it must be admitted that even partial and late reactions are unwelcome and disturbing, even if an observer thinks that his skill and experience will enable him to avoid mistakes from their occurrence. It may also well be, as suggested by C. Fraenkel, that Stern's and Kühnau's normal and non-typhoid cases include not a few who had recovered from unrecognized typhoid infection, and this supposition is the more probable in consequence of the prevalence of typhoid fever in Breslau. Stern himself calls attention to the liability of failure to recognize certain mild cases.

There have been a few cases reported in which the diagnosis of typhoid fever was made on the basis of the serum reaction, but which the authors, from subsequent developments, considered to be free from typhoid infection. It has been claimed, therefore, that positive serum reactions are not a sure sign of typhoid fever, although no one claims that the chances of error from this source are more than slight. The cases reported by Achard and Bensaude, Jez, Ferrand, du Mesnil and van Ordt have given rise to the most discussion. For what seem to me justifiable criticisms of these reports, I would refer especially to the papers of Widal and of Stern, and I will limit my remarks to some general statements concerning such alleged failures of the serum test.

In the first place, as the matter now stands, positive reactions obtainable only with dilutions lower than 1 to 50, possibly than 1 to 60, especially if the reaction is partial and late in appearance, are not certain diagnostic signs of typhoid fever. In most of the cases just referred to no exact quantitative estimations of the agglutinative strength of the serum were made, and hitherto it has not been shown that the reaction ever occurs with non-typhoid serum in dilutions exceeding 1 to 50, with observance of other quantitative points which I have already considered. With the limited number of observations, however, which we now possess, we can not, of course, say but that such cases will be found in the future.

In the second place, infection with the typhoid bacillus can not be positively excluded either on clinical grounds alone or by anatomic examinations at the postmortem table. Infections with the typhoid bacillus occur without any characteristic anatomic lesions. There may be entire absence of ulcers or other lesions of the intestine. We have recently had at the Johns Hopkins Hospital a case with positive serum reaction, from which Dr. Flexner cultivated, in large number, typical typhoid bacilli from the gall bladder although there was no previous history of typhoid fever, and there were no intestinal lesions. In 1891 I called attention to the favorable conditions offered by the bile for the prolonged survival of the typhoid bacillus. In one case I was able to demonstrate large numbers of typhoid bacilli in the bile of a rabbit, 128 days after intravenous injection of 0.5 c.c. of a bouillon culture[4]. Pick has reported a case with marked positive serum reaction in which at the autopsy no typhoid intestinal lesions and no swelling of the spleen were found, but bacteriologic examination showed the presence of typhoid bacilli, not however in the spleen. Guinon and Meunier's case is instructive. During life the symptoms were those of acute miliary tuberculosis and typhoid fever combined. Serum reaction was positive. At autopsy the lesions appeared to be only those of acute miliary tuberculosis, small ulcers in the intestine being typically tubercular in aspect. Typhoid bacilli, however, were cultivated from the spleen and other parts. As both the symptoms and the bacteriologic examination indicated that the typhoid infection was in course of disappearance, the case, if examined at a somewhat later period, might readily, as Guinon and Meunier remark, be placed to the discredit of the positive value of the serum test. We are justified, in the light of such cases as these, in demanding that thorough bacteriologic examinations be made before cases which have given during life the characteristic serum reaction, but which do not present at autopsy the anatomic lesions of typhoid fever, be recorded as free from infection with the typhoid bacillus.

In the third place, the difficulty of excluding a previous attack of typhoid fever, after which, as already stated, the specific serum reaction may persist for years, is to be borne in mind.

In conclusion, I would emphasize the following practical points:

1. Experience has demonstrated that the method of serum diagnosis of typhoid fever is of great practical value.
2. The alteration of the blood on which this method is based, is a specific effect of infection or intoxication with the typhoid bacillus.
3. The microscopic serum test is to be preferred to the macroscopic methods.
4. Quantitative determinations, relating especially to the culture, the time limits, and the dilution of the serum. are of importance and, at least in doubtful cases, should not be neglected.
5. As the reaction may be delayed or occasionally absent, a negative result of the test does not exclude the diagnosis of typhoid fever. The later in the course of the disease the test is applied, and the oftener the examinations are repeated at intervals, the less is the probability of the existence of typhoid fever.
6. The persistence of the reaction, sometimes for years, after recovery from typhoid fever, is to be borne in mind in interpreting the reaction in febrile conditions. The appearance of the reaction and its increase during the period of observation speak for fresh typhoid infection.
7. The danger of mistakes from positive reactions in non-typhoid cases can be guarded against in nearly all cases.
8. Provision should be made, especially by the establishment and support of municipal or State laboratories, to render generally available to practitioners the serum method of diagnosis, as well as other bacteriologic procedures of similar practical value.

A CLINICAL STUDY OF WIDAL'S SERUM DIAGNOSIS OF TYPHOID FEVER.

Presented to the Section on Practice of Medicine, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY JOHN H. MUSSER, M.D., AND JOHN M. SWAN, M.D.

PHILADELPHIA, PA.

The method employed was as follows: A drop of blood was taken from the previously cleaned finger of the patient suspected to be suffering from typhoid fever. This drop of blood was allowed to dry on a cover-glass or microscopic slide and was then taken to the laboratory.

The dried blood was dissolved in one drop of distilled water, at the time of making the test. One platinum loopful of this solution was added to nine platinum loopfuls of a pure bouillon culture of the typhoid bacillus, which was not more than twenty-four hours old. This mixture was then studied in the hanging drop.

These drops were examined from time to time until it was definitely established that the reaction was present or absent. In case the motility of the organisms was still present in the evening, when the light failed, the preparations were put aside in a warm room until morning when they were again examined. If motility was still present and there was no formation of clumps the reaction was definitely considered to be absent.

Early in the course of the examinations, instead of using a solution of blood which had been previously dried, the drop of blood was allowed to coagulate on the slide and then the serum was drained to one side and the bouillon culture added. This technique produced several faulty results because the undiluted blood serum was liable to cause agglutination on account of the normal agglutines contained in the blood.

---

[4] Welch: Bulletin of the Johns Hopkins Hospital, August, 1891.

At first the bouillon cultures were grown over night in the incubator, at a temperature of 37 degrees. Later the inoculation into bouillon was made in the afternoon and the tube was carried in the vest pocket for several hours and then left in a warm room over night. This method gave a bouillon culture which was particularly suitable for the performance of the test and from which much better results were obtained than from cultures grown by the former process.

In this manner one hundred tests have been made. The blood was taken, in nine cases, from children under 15 years of age and in ninety-one cases it was taken from adults. Twenty-six of the patients from whom blood was taken were females, and seventy-four were males. The age or sex of the patient seemed to make no difference in the reaction. The results of the examinations will be classified under the following heads: 1. Cases of typhoid fever in the course of the disease. 2. Cases of convalescent typhoid fever. 3. Cases in which typhoid fever had been present at some previous time 4. Cases in which typhoid fever was absent.

1. Thirty-five examinations were made of typhoid fever blood, the patient being in the disease and the temperature ranging from 99.6 to 104.6. The reaction was present in all except four cases.

In one instance (obs. 25) the reaction was imperfect, there being a tendency to the formation of clumps of bacilli, but the clumping being irregular and numerous motile bacilli remaining distinct between the groups. This observation was made on the fourteenth day of the disease, at a time when the temperature was 102. Later on in the disease, on the twenty-third day, when the temperature was 102.2 the reaction was present and perfectly developed. In three cases the reaction was absent (obs. 32, 33 and 35). In one of these the examination was made on the third (obs. 35), in another on the fifth (obs. 32), and in the third on the seventh day (obs. 33).

The earliest observation made was on the third day of the disease (obs. 35), and the reaction was then absent. One examination was made on the fifth day and the reaction was absent (obs. 32). Two examinations were made on the seventh day. In one of these cases the reaction was present (obs. 4), and in the other it was absent (obs. 33). The reaction was apparently not affected by cold bathing. Concerning this point, however, the observations have been too few and not sufficiently accurate.

2. Twenty-four observations were made on the blood of patients convalescent from typhoid fever. In these cases the temperature ranged from 99.6 to 97, with two exceptions. In one of the excepted cases the temperature was 103, and was due to an attack of tonsillitis; in the other the temperature was 102.8, and was caused by an attack of post-typhoid meningitis, of which the patient finally died. At the autopsy in this case, healing typhoid ulcers were discovered. Of these observations, the reaction was present in eighteen cases, imperfect in four cases, and absent in three cases. The cases in which the reaction was still present were examined from the twenty-fourth to the sixty-seventh day after the commencement of the disease. In the cases in which the reaction was imperfect, thirty-four, one hundred and four, fifty-eight and one hundred and five days had elapsed from the beginning of the disease. Thirty-eight, eighty-seven and sixty-two days respectively had passed since the beginning of the disease, in the cases in which the reaction was absent.

3. Seven examinations were made of blood from patients in whom typhoid fever had been present at some previous time. A patient who was being treated for chlorosis presented a distinct reaction, and on inquiry it was found that she had suffered from typhoid fever ten years previously.

On a second patient who had suffered from typhoid fever in September, 1896, three examinations were made. Once the reaction was present, once imperfect and once absent.

In the cases of two nurses, who had suffered from typhoid fever in 1893, the blood showed the reaction in one, while the reaction failed to appear in the other. The nurse whose blood showed the reaction had had a more severe attack of the disease.

In the case of a man who had suffered from typhoid fever in January, 1897, the reaction was absent.

4. Thirty-five examinations of blood from patients suffering from other disease than typhoid fever were made. The reaction was absent in all these cases. The diseases from which the patients were suffering were varied. Two cases only of tuberculous disease were obtainable. The blood of these gave a negative result when the test was made. Examinations with negative result were made in two cases of catarrhal fever. A varying list of diseases of the alimentary tract were examined with like negative result. It is a matter of regret that the blood from a case of acute miliary tuberculosis could not have been tested. The blood from eight cases of pneumonia was examined and in each case was the reaction absent.

CONCLUSIONS.

1. The age or sex of the patient does not make any difference in the character of the reactions.

2. The reaction may be obtained from the blood of cases of typhoid fever during the course of the disease, and may be found as early as the seventh day. In some cases it is absent at the seventh day and in other cases it is not fully developed until later in the course of the disease. In no case was it found earlier than the seventh day. In another case it was not perfectly developed on the fourteenth day.

3. The reaction disappears at a varying time after the cessation of the disease. The bacilli may fail to agglutinate as early as the thirty-eighth day. The reaction may be perfect as long as ten years.

4. The reaction can not be obtained from the blood taken from patients suffering from diseases other than typhoid fever, unless there has been a previous attack of the latter disease. Even if there has been a previous attack of typhoid fever the reactive property of the blood may have disappeared.

5. The test is valuable in diagnosing between typhoid fever and other diseases presenting a so-called "typhoid state." This is particularly the case in tuberculous diseases, in catarrhal fever, and in pneumonia.

6. From the observation of the one hundred cases it would seem that the reaction was accurate and that

it could be relied on. It presents advantages over former clinical methods in doubtful cases.

The pure cultures of typhoid bacilli were obtained from the Laboratory of Hygiene of the University of Pennsylvania, and thanks are due and are here extended to Dr. Abbott for permission to obtain them and to Dr. L. W. Peckham for making the inoculations.

The specimens of blood which were subjected to the test were obtained from patients in the wards of the Presbyterian and Episcopal Hospitals.

CLINICAL REPORT ON SERO-DIAGNOSIS.

Presented to the Section on Practice of Medicine at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY R. C. CABOT, M.D.
BOSTON, MASS.

I have collected and placed upon the blackboard the statistics relating to sero-diagnosis from all parts of the world, so far as I have been able to get hold of them, including those of good, bad and indifferent technique, and therefore open to criticism. The figures, as you see, show a very large proportion of successful serum tests. Out of 1,826 cases supposed to be typhoid, the result of the serum test was confirmed by autopsy or by the subsequent course of the case in 1,740, or 95.2 per cent. Out of 1,649 cases known to be other than typhoid, the serum reaction was negative in 1,592, or 96.5 per cent. Out of a total of 3,475 cases examined, in 98.8 per cent. the results of the serum test have been borne out by the court of ultimate appeal, the clinician. These are the combined results of seventy-one articles, twenty-five American, twenty-two French, fifteen German, five English and four Italian. About two-thirds of all these cases have been reported by American observers.

My own experience relates to a little over 400 bloods. It has been the experience of the practitioner, and not of the laboratory worker. I have had to do these cases entirely by myself. A large proportion of them have been cases in private practice and I have been able personally to follow every case. In that respect it is a somewhat better series of cases to judge from than those which have been placed under the control of somebody else. My personal results are as follows: In 101 cases supposed to be typhoid I got the reaction by serum in 96. I failed to get the reaction in 5. Of those 5 cases, however, 3 were seen late in the disease. One was seen only early in the disease and died the day after the reaction was tested. In one case the result was persistently negative throughout; there was never a typhoid serum reaction despite every evidence, except the evidence of autopsy, that it was a case of typhoid fever.

Three hundred and one cases were tested which were known to be other than typhoid fever; 300 were negative, 1 was positive. The single case, which occurred the day before I came to Philadelphia, which therefore I have not had opportunity to follow up, was a case of pernicious anemia in a negro. The clumping was prompt in a 1 to 20 dilution. I have not tried a dilution higher than that. Therefore it does not constitute a surely negative test according to the definition of Professor Welch. Out of 301 cases 300 were negative. The list included every variety of disease such as one sees in the Massachusetts General Hospital, going through the wards at random. It includes a considerable proportion of our epidemic of cerebrospinal meningitis, seventeen cases of which I have tested, always with negative result. I have taken the blood in almost every case from the ear, using a single drop of blood taken with the medicine dropper and put directly into a small tube containing ten drops of the bouillon culture of typhoid taken with the same dropper. This is not a strictly accurate method, but it seems to me to be sufficiently accurate. It is the quickest and simplest method I know of in that only one drop of blood from the patient is necessary, the puncture is trifling and it can be repeated without troubling the patient as would occur if more blood were taken at each test. The culture is taken in the test tube to the bedside. I have used bouillon cultures, taking care that the bouillon should be as nearly neutral as possible, using stock agar culture transferred once a week; the secondary cultures were either twenty-four hour cultures in the thermostat, or two, three or even four days old kept at room temperature. Bouillon cultures kept at room temperature preserve their motility and apparently their usefulness for this test, for considerably longer periods than if they are kept in a thermostat. And it is also true that the organisms are considerably more sparse, so that the disadvantages of the method mentioned by Dr. Johnston are partially avoided. I have found that the more rapid the motion the more reliable the culture in the technique which I have used. I think it has been very rightly insisted upon by Dr. Johnston, that one man should stick to one technique and work out the advantages and the disadvantages of that technique if he wishes to get the best results. I have not done that myself, but I think that when a man gets a technique he should stick to it in order that he may know the advantages and the disadvantages of his own method.

I have used a dilution of 1 to 10, which, as Professor Welch has said, is now generally thought to be too low a dilution. I think that that question depends entirely on what the length of the time limit is. Most German observers who have condemned the 1 to 10 dilution, have used either no time limit at all or a much longer time limit than that which has been my practice. From fifteen to thirty minutes has been the limit in my cases within which the reaction must occur if it is to be considered typhoid reaction. With the exception of the one case of pernicious anemia, I have met no case other than typhoid in which the typhoid reaction was given by this method. I have used exclusively the quick or extemporaneous microscopic method, never the twenty-four hour method. The testimony of observers who have tried both has been almost overwhelmingly in favor of the quick method, and it has not seemed to me worth while to test the twenty-four hour method considerably.

As to what constitutes a reaction, I agree entirely with what Dr. Johnston has said, that a cessation of motion with clumping is the most satisfactory, and that either clumping without cessation of motion, or cessation of motion without clumping, is to be looked upon with suspicion and the case is to be subject to further test. I think it can not be too strongly insisted on that every culture should be examined every day before a series of typhoid tests is made, with reference to the existence or non-existence of clumps in that culture before any serum is added. This would not be true, perhaps, were the laboratory conditions quite as favorable as possible. If that is done it throws out, I believe, one of the greatest sources of error in this reaction as tried by the general practitioner.

The question arises, How early does this reaction come on? The statistics of different observers are different upon that point. In my own series of thirty cases, in which the patient was seen between the first and the seventh days in bed, twenty-six, or 85 per cent. gave the reaction. One point which seems to me worth discussing is, What constitutes the first day of a typhoid case? I have yet to see any observer who has adequately explained what he means by the first or any other day of typhoid fever. With reference to this reaction, we all know how difficult it is to fix that point. So it seems to me that in reporting statistics we must adopt some fixed rule. I have called the first day in bed the first day of the disease, without meaning that it really is the first day. But, for the purpose of statistics, the first day in bed is as good, or perhaps as little open from criticism, as any other which has been used.

Using that standard, the first day in bed as the first day of the disease, the reaction has been present in the first week in 85 per cent. of my cases. In those reported by Professor Biggs and Professor Park, I believe 63 per cent. was the figure during the first week. In those reported by Elsberg it was only 8 per cent. We need further evidence on this point. Out of the whole number of cases which I have collected there were fourteen in which the reaction appeared very late for the first time, anywhere from the fourteenth day of the disease on to the second week in convalescence. In two of my own cases the reaction was always absent until relapse. It was absent on repeated examinations throughout the whole of the original attack, and present only in relapse. Of the remaining 101 cases it was present sooner than the twelfth day. I have seen the reaction in one case two years after the typhoid attack. There are about sixteen cases on record of these very late reactions, occurring later than eighteen months. The longest period which I have seen carefully recorded was thirteen years.

A source of error which I think has not been referred to is the fact that the reaction is intermittent; that it may appear one day, be absent the next, and present again the third. And this adds to the difficulty of interpreting the meaning of a negative reaction. A negative reaction may mean one of various errors in technique; it may mean that the reaction has not yet appeared and may appear later. It may mean the reaction has been present but has disappeared.

With regard to the presence of this reaction in the blood of negroes who have not had typhoid fever, a number of observations are on record. Dr. George B. Shattuck of Boston found a positive reaction in two who were not known to have had typhoid, although there was some uncertainty in the history. He found there was reaction in three others whom he was quite positive had not had typhoid fever. In other negroes who had not had typhoid fever he did not get the reaction.

This test is not available for prognosis, in my opinion. The great majority of those who have studied the test have agreed that it is not regularly more marked in severe cases than it is in mild cases. In a general way severe cases tend to have a little surer and stronger reaction, but it is not a rule, and the test can not be used for purposes of prognosis.

A word as to the possibility of this test being used be the general practitioner. I think there is no doubt that, for the greatest accuracy of results, the test should be performed in laboratories by laboratory specialists. But I think it can be performed with *sufficient* accuracy to be a very material help in diagnosis by the ordinary practitioner who has familiarized himself somewhat with the methods of modern bacteriologic work. I think the reaction can be made at the bed-side of the patient, and with a good deal of accuracy if proper precautions are carried out, and I think it is of very material aid to diagnosis, even with the inaccuracies which are necessary when the test is not performed in a laboratory and by a trained bacteriologist.

OPEN DISCUSSION ON THE SEVERAL PAPERS ON TYPHOID FEVER.

Dr. **William Osler** of Baltimore—The question of meningitis in typhoid fever is an extremely interesting one. Dr. Ohlmacher's[1] is the first communication presented in this country in which the typhoid bacillus has been definitely demonstrated in the meningeal exudation. It is an excessively rare complication. I have never met it personally, and I have records of over one hundred autopsies of typhoid fever. The interesting point is that in neither of these cases reported by Dr. Ohlmacher were there any clinical suggestions as to the occurrence of meningitis. Clinically I have seen meningitis diagnosticated in many cases, but as Stokes pointed out many years ago, there are no definite criteria by which we can make an absolute diagnosis of menigitis in typhoid fever. Just as in the cerebral type of pneumonia, so in the cerebral type of typhoid fever, there may be every symptom of meningitis, even to retraction of the head and jerking of the arms, without one single cubic centimeter of exudate being found at autopsy.

The question of perichondritis touched upon by Dr. Fussel is one of considerable interest, particularly with reference to perichondritis, not internal, but external to which the author did not allude.

Dr. McCormick is still a young man, and I have no doubt that with his years his experience will increase also. There is no good whatever in bringing forward lists of cases without a death. I have had fifty-three cases of typhoid fever without a death under the Brand treatment. My late colleague, Dr. Stewart, at the Royal Victoria Hospital, Montreal, has treated 130 consecutive cases by the Brand method without a death. One thing which I think indicates that Dr. McCormick is a young man is, that he should go on treating typhoid fever by his method when having 19 per cent. of hemorrhages. Had I 19 per cent. of hemorrhages in my treatment of typhoid fever I would change it next year for something much less risky.

As to opening the bowels in typhoid fever, I would like to open the minds of the profession in this country with reference to that point. Take a long series of cases, five or six hundred, take from among them the cases in which there has been constipation, cases not treated with calomel, not treated with intestinal antisepsis, and I will guarantee that the cases which have run the shortest course, which have given the least trouble and the least mortality, are these cases in which there has been constipation. I always hope that if any one special symptom is to develop it may be constipation.

Dr. **John Cronyn** of Buffalo, N. Y.—Out of sixty-five cases, of typhoid which I have seen this winter there was this kind of relapse in four. I would ask Dr. Osler whether the latent poison which redevelops in the patient who is almost a convalescent is in the spleen or glandular structure of the intestine, or somewhere else. Two of my patients were up and about the wards; they lost their appetite, became feverish, and began—this is a symptom to which I wish particularly to call attention—to have a little cough as if they were going into acute tuberculosis. It took them a much longer time to recover after this relapse than it had before to reach convalescence. The treatment used after the relapse was directed entirely toward the spleen and the general system; a mixture of iron and quinin, proper nourishment, followed by ultimate recovery.

Dr. **J. M. Allen** of Kansas City, Mo.—I regard typhoid fever as a self-limited disease, and when cut short it is not the result of medicine but of difference in individual power to resist the germ. There is no other disease in which good, sound medical knowledge and practical experience tells so well as in typhoid fever. I enter protest emphatically against the calomel purgative course of treatment. I believe there is something in intestinal germicide remedies, but I have not seen that this or any other system of treatment will cut short this disease. I desire to endorse Dr. Osler's statement because as you may know, I can go back to the period when it was considered safe to let the bowel remain closed, if you please for a week, and the percentage of recoveries in that class of cases was always large. When there is constipation it carries with it a positive idea that the pathologic condition is limited. Hence the chances for recovery are better. I do not mean to say that the patient should not have an action of the bowel once in twenty-four hours, but I do wish to say that there is not the slightest necessity for his having more than one action in twenty-four hours. The general plan of treatment should be one of practical common sense: one case with water, another with something else, using all the remedies which have been mentioned, according to circumstances. There is no place that the physician realizes the statement of the great Dr. Watson more fully than here, that in obviating the tendency to death he has treated the case masterfully.

Dr. **Fowler** of Pennsylvania—I am almost amused at Prof. Osler's criticism of Dr. McCormick's paper. The Professor says that if he had 19 per cent. of hemorrhages from any plan of treatment he would abandon it as soon as possible. I would take this ground: If I had a certain number of cases of typhoid fever of such severity that nineteen of them had hemorrhage, and severe hemorrhage at that, and they got better in spite of it, I would stick to my plan of treatment notwithstanding.

Dr. **Herrick** of Cleveland—It is obvious to me that there are two classes of inquirers with regard to this disease. One comes to the disease with the microscope in the hand, the microscopist who sees it with that instrument. Another class includes the macroscopist, who sees the coarse characteristics of the disease. Most of the gentlemen here, I presume, come to this subject as the macroscopist. Now, the facts are that this is a disease of an organ, and there is no question but what that organ has a peculiar relation to the whole system, and that relation gives rise to the phenomena which we observe in typhoid fever. It is an enteric fever. We are all agreed as to that. Whether it is due to an infection, or whether the infection comes subsequent to inflammation of the glands is a matter of some interest. I will not discuss that. I am ready to accept both theories. The infectious theory is a working hypothesis for sanitation. I would take all precautions against infection. There is inflammation of Peyer's glands. What is the danger from that? There is danger of sepsis being carried through the tumefied glands into the general circulation. Let us apply common sense to the treatment. I can approve of the treatment advised in the several methods in some instances, for there are no two cases alike. You can not classify the disease as you can the plants of a garden. I would urge the necessity for holding to our physiology and anatomy in their application to this disease. Call it infection, call it inflammation, but there is a local infection, and there is no fever until that local infection has been carried into the circulation. All agree on that point.

As to treatment, it should be as simple as possible. The digestive organs are the ones affected. There is no better principle to carry out in inflammation than rest. Put the patient in bed. Put the digestive organs absolutely Do not fill up the bowel with milk, or meat, or those things that constantly irritate the bowel. With regard to medication, I do not care if it is only water, pure water, and given abundantly outside or inside. I prefer it inside. I do not believe in Brand. I do not believe in being chained down to Brand's method, or Woodbridge's method, or anybody else's method.

---

[1] Paper recently received, will be published very soon. [Ed. Journal.]

Dr. ANDREWS of Pennsylvania—I should like to counteract the influences of the statement made by Dr. McCormick that opium should not be used in hemorrhage of the bowel in typhoid fever. I trust the medical profession will not lose sight of that leading principle in surgery as well as in medicine, that the first requirement in all cases of hemorrhage is absolute rest of the part. It is just as necessary to arrest peristalsis where hemorrhage occurs, or seriously threatens, as it is to quiet the heart in hemoptysis.

Dr. J. E. WOODBRIDGE of Cleveland, Ohio—The gentleman who read the paper did not follow my advice, or did not quote me correctly in every instance. I certainly never said that one dose would cure a patient. One gentleman says that reports of cases are of no value. How, then, are you to establish any theory in medicine? If in one epidemic they have a certain percentage of deaths, and in the following epidemic they have no deaths by a different method of treatment, is that not some evidence that the different method is better than the one first employed, especially if the duration of the disease is greatly shortened? If in the hospital in Massachusetts they had a very large death rate, they changed the method of treatment and had no deaths, and the same physician who applied the treatment in the hospital also applied it in private practice and had no deaths, quite a large number of cases having been treated, is not that some evidence that the one method is better than others, especially when all his brother practitioners using former methods had the same death rate as in previous years? Such instances could be multiplied indefinitely. The cases are numerous.

I have used Professor Osler's name, and I fear he has misunderstood the manner in which I have used it. I wish to say that I used it in the most complimentary way. I took him as the representative of the best thought of the medical profession of the United States and of the world when I quoted him. I have been accused of saying many harsh things, but I want to say that I never said a harsh thing about any member of the medical profession until I was driven to it by harsh duty. Leading members have continued to write me and ask about my management of typhoid fever. I would like to read one letter from a gentleman of wide experience, who said he proposed to write me about my views and apply the method as closely as his intelligence would permit, and if he found that I had misrepresented facts, if he found I did not give him a correct statement he would denounce me before every medical society in the land. He writes me that since commencing the treatment of typhoid fever by this method he has employed it exclusively and he would not now use any other. All of the patients recovered; none had sequelæ. In one the temperature went two or three degrees higher within two days after beginning the treatment, but it then came down and the patient made an early recovery. That is only one letter out of perhaps fifteen hundred which I have received from various physicians. If I am wrong, there are a great many physicians in the United States who are wrong. The gentleman whose letter I have quoted has charge of a hospital through which thousands of cases pass annually; he knows typhoid fever when he sees it, and he would have denounced me if he had not secured the results which I had promised.

As to one remark of Dr. Osler—I beg his pardon—that cases of typhoid with constipated bowels did better than those with diarrhea. The diarrhea of typhoid is evidence of poison, and if the patients are treated by the antiseptic system there can be no diarrhea, but every single case will be constipated. If antiseptics are properly used it is not possible to have diarrhea, or to get along without using saline laxatives in addition to the little tablets.

Dr. OSLER—Could you not have diarrhea from fermentation?

Dr. WOODBRIDGE—In the antisepticised alimentary canal you can not have diarrhea. You will have constipation in spite of all you can do, and you will have to fight that from the beginning to the end of the disease. I can give these tablets and get up passages next day; I may get them the day following, but not on the fifth, sixth, seventh or eighth day. You can not give enough of the tablets for such an effect. In one hospital it was said they were given ten at a dose, yet it was necessary to give Hunyadi water. Those are only a few facts.

Dr. ——— —I have looked into the Brand system, and have been much pleased with the results. It is applicable to the hospitals in our large cities. Now we need something which can be applied by the country practitioner in houses where there is no bath tub. If we can get just as good results from the Woodbridge method, or the McCormick method, let us have both of them tried. I feel that the professors in our great hospitals would do a very great service if they would put these several methods on trial side by side in our great hospitals, and announce the result for the benefit of the general practitioner. It is a notorious fact that physicians are so prejudiced against the antiseptic treatment that they are afraid to give it a trial.

Dr. McCORMICK—It would appear to be a piece of presumption on my part, being but a country doctor, to read a paper here that would in any way lead this Association to believe that the college professors and the makers of text books were not teaching the proper teaching. But, somewhere early in my education as a physician, I conceived the idea that the cure of disease was the ultimate object and aim of the physician, and on that basis I have practiced medicine ever since. So far as the hemorrhage of typhoid fever is concerned, I wish to say to my friend, Professor Andrews of the Medico Chirurgical College, that no stronger impulse to abandon opium was ever made upon my mind in case of hemorrhage in typhoid fever, than when I was called in consultation by a young man who had just left his college to see a woman who had had hemorrhage and had lost considerable blood. The doctor gave this woman a hypodermic injection of a quarter of a grain of opium. At the end of fifteen hours she had another hemorrhage and he gave her another injection. After this I saw her in consultation. She was swollen like a drum. I said I thought I would not have given her the second dose. He replied that he was never taught anything else. That woman died, and I am as firmly convinced as I have existence that she would not have died if she had not received that injection of morphin. If one single principle has been demonstrated in medicine it is that opium and morphin are no longer the agents with which to treat inflammation in the abdominal cavity. The surgeons long since taught us that we must stop giving opium in these diseases, and if we must stop giving opium in surgical diseases, why not more so in medical diseases? I believed the college professor was infallible; I believed the text books were infallible. But when my patients died under the treatment they told me to give them I made up my mind something was wrong.

Dr. OSLER—As to college professors and authors of text-books, they are just as fallible as the rest, just. But they have eyes and ears, and some of them common sense, and those who have common sense when they have a case of typhoid fever which is bleeding will give opium and morphin.

SUMMARY OF VIEWS EXPRESSED AT THE DISCUSSION ON SERUM DIAGNOSIS AT THE MEETING OF THE AMERICAN MEDICAL ASSOCIATION AT PHILADELPHIA.

The committee appointed by the Chairman of the Section on Practice of Medicine make the following report:

1. In selecting the material used in making the test the choice between: a, serum, b, dried blood, c, fluid blood, and d, blister fluid, will depend largely upon whether the object be scientific research, clinical diagnosis in hospital or private practice, or public laboratory diagnosis where the samples have to be sent some distance.

2. In spite of considerable variation in technique, there has been a remarkable uniformity in the results obtained by those taking part in the discussion, and their average of about 95 per cent. of successes agrees with the general average of the cases, nearly four thousand, thus far recorded in medical literature.

3. Each of several methods of technique advocated may thus give good results in the hands of those thoroughly familiar with the details found necessary in each case and the sources of error to be avoided, success depending rather on being perfectly familiar with one method than on the particular one selected.

4. For routine diagnostic work even the very simplest methods may give good practical results, but for recording scientific observations those methods which are accurately quantitative should be selected. This is especially necessary in reporting exceptional cases at variance with the general results recorded or where the observations are made the basis of generalizations.

5. A complete reaction should comprise both characteristic clumping and total arrest of motion occurring within a definite time limit. For practical diagnostic work a dilution of 1 to 10, with a fifteen minute time limit, is convenient. In any doubtful case the dilution should be carried as far as 1 to 50 or perhaps 1 to 60, and a reaction not obtainable at that point should

not be regarded as perfectly conclusive. For these higher dilutions the time limit should be extended to two hours.

6. Intensity of reaction in a given serum should be estimated by determining the degree to which it may be diluted without losing its power of giving a decided reaction, both as to agglutination and loss of motion.

7. The intensity of reaction shown by the same serum is influenced by the age, condition and virulence of the test culture and by the composition and reaction of the culture medium. For purposes of comparison the sensitiveness of the test culture should be taken into consideration.

8. The evidence so far recorded establishes that the reaction may be delayed or occasionally may not be obtained in cases of genuine typhoid infection; and also that it may be exceptionally present in non-typhoid cases, though not in an intense degree.

9. In investigating exceptional and contradictory results the following circumstances have to be considered: *a.* The uncertainty of clinical diagnosis. *b.* The absence of bacteriologic or other confirmatory methods of diagnosis during life, giving decisive negative results. *c.* The possibility of overlooking typhoid infection even postmortem, in the absence of characteristic intestinal lesions where a very thorough bacteriologic examination has not been carried out.

10. The modifying influences mentioned above suffice to explain the divergencies existing in the reports of different observers. Without being absolutely infallible the typhoid reaction appears to afford as accurate diagnostic results as can be obtained by any of the bacteriologic methods at our disposal for the diagnosis of other diseases. It must certainly be regarded as the most constant and reliable sign of typhoid fever, if not an absolute test.

N. B. The above summary, while expressing the general consensus of opinion brought out during the discussion on serum diagnosis before the Section on Practice of Medicine of the AMERICAN MEDICAL ASSOCIATION, does not claim to represent exactly the individual views of any one of those who took part.

NEUROLOGIC PROGRESS IN AMERICA.

Presented to the Section on Neurology and Medical Jurisprudence, at the Forty-eighth Annual Meeting of the American Medical Association, at Philadelphia, Pa., June 1-4, 1897.

BY C. H. HUGHES, M.D.
ST. LOUIS.

America has contributed much to the creation of modern neurology, especially to neuriatry or clinical neurology. By the term neurology I include normal neurology and abnormal neurology, which I term neuriaty, and psychology and its opposite morbid aspects psychiatry. In this great historic city one of its most honored names in medical and political history, Dr. Benjamin Rush, was the pioneer psychiatrist and neuriatrist[1] (if you will permit the coinage of this word) of the century. The consideration of mental aberration received much attention at his hands. It was here that insanity first had a hospital set apart to its victims, and inebriety was treated as a disease under the name oinomania. This great physician and statesman made a study of alcoholism, its causes and consequences and boldly proclaimed it the drink disease in advance of all the world, just as Ephraim McDowell in Kentucky had boldly cut into the abdominal cavity and made the first successful laparotomies, thus opening the way to the greatest of the present life-saving triumphs of modern surgery, as he had also opened the way for that great declaration of principles that made this a free independent and invincible nation.[2]

No record of American medical progress, no tribute to American medical glory is complete without Pennsylvania, and no literary monument commemorative of the the profession's grandeur and honor could stand whose pedestal is not placed in this city of medical greatness and brotherly love. He not only took a seat in the Continental Congress and made a preliminary draft of and signed the final Declaration of Independence, but he laid the foundation, with his eminent colleagues, broad and deep for the first, and still living and vigorous, American medical college. But he did more in neuriatry than I have mentioned. He recognized the neuropathic diathesis which he called the "phrenitic predisposition," "a union of diffusive morbid irritability involving the nerves and that part of the brain which is the seat of the mind," and he notes the disposition and capacity of certain lunatics to simulate sanity for a purpose. He also notes how the incipient delusions of the insane are mistaken for the cause and relates a case of delusional mental infidelity in a woman "of great medico-legal significance" (*op. cit.*, p. 44). He recognized and named a phase of affective or moral insanity before the term had been invented in what he called the lieing disease.

Rush's definition of illusion, "a waking dream," is the briefest on record, and his amplification of it, as "a false perception, in the waking state, from a morbid affection of the brain," is perhaps the best on record. His presentations of the morbid aspects of love, grief, joy, fear, anger, reverie, the moral faculties and, in fact, of all the passions and of the morbid state of the sexual appetite, are unique and advanced for his day; described in 1793 a sexual pervert who answered the doctor's question as to desire and excess thus: "*Dixit per annos tres, quinque vices, se coitum fecisse in horis viginti quatuor, et semper semine injecto,*" antedating the records of Arnold, Krafft-Ebing and others on this subject.[3]

He was familiar with sexual tabes dorsalis, hypochondriasis, etc., and from 1804 to 1807 records four cases of madness due to onanism. He took the psycho-somatic view of insanity, such as the best alienists hold today, saying that "did cases of madness reside exclusively in the mind, a sound state of the brain ought to occur after nearly every death from that disease," whereas he know of "but two instances upon record of the brain being found free from morbid appearances in persons who have died of madness."

Here is sound modern psycho-pathology and a correct psycho-somatic conception of the nature and definition of insanity such as we hold today. He denied that insanity was "an ideal disease" and asserted that "epilepsy was a bodily affection."

He had a correct conception of aphasia as a brain trouble, though he neither knew its precise seat nor its name as we call it today. Although he believed too much in venesection, as we believe too little, his therapeutics for acute violent mania, venesection, solitude, seclusion and rest, acts of justice and a strict regard for truth, "everything necessary to their comfort and every promise made to them faithfully performed," is good, *fin de siècle* pyscho-therapy, except that we have therapeutic substitutes for blood-letting not known to this archiater in physiologic medicine. He was the American pioneer in the modern management and treatment of the insane and the world's pioneer in correctly understanding and providing for the inebriate as a brain-damaged man. He was the world's champion of the mobid inebriate's rights and demanded for him hospitals for treatment like other sick persons. "They are as much objects of public humanity and charity as other people," he said (*vide op. cit.*, p. 267). He invented the tranquilizing chair as a more humane substitute for the straight jacket, and his law of kindness with his patients is now the modern rule of action for all hospitals for the insane. Rush's record might be further extended, but enough has been said to name him among the immortals in medicine and philanthropy as he is among statesmen. His name was not born to die whether Congress builds or neglects to honor Washington with his statue.

---

[1] I certainly think the time has come for the invention and use of this term. A term I have employed for many years in my lectures, explaining its derivation and necessity.

[2] Though not germane it is a source of professional pride to note the historic fact as a "member of the provisional conference of Pennsylvania and chairman of the committee to which was referred the great question whether it had become expedient for Congress to declare Independence," he made a "report which was adopted and sent to the Congress the same day." This was a "most animating document, most probably written by Rush, as he was chairman of the committee and ever ready with his pen." The whole committee consisted of himself and Col. James Smith, and "included all that has been so much praised in the declaration attributed to Thomas Jefferson, of which it might appear to have been the protocol" (Stone's "Eminent American Physicians and Surgeons," p. 137). Rush also went into the Continental Congress, knowing he was to vote for independence, for he was el[illegible] to fill a vacancy created by the resignation of a member who de[illegible] to remain and vote for separation.

[3] Vide p. 345, "Diseases of the Mind," Philadelphia, 1812.

Surely the profession of America and especially of this great city should be proud of having had in its ranks this far-seeing philanthropic physician.

Before leaving this subject we here note the fact in parenthesis that Robley Dunglison, also a Philadelphian, in earlier editions of his classic medical dictionary, has informed us that such a nervous condition as nervous debility existed and even gave us the name of neurasthenia with the long accent on the i.

The first systematic treatise devoted exclusively to the medical jurisprudence of insanity in any language was written by the friend and the benefactor of my youth, Dr. Isaac Ray of Philadelphia, a work still recognized as high authority in American and foreign courts. Ray's exposition of the clinical features of insanity are clear and concise. His delineations of its affective forms have never been surpassed, while his pleas for justice to the insane have been so masterly and forceful as to markedly modify the practice of American courts in the direction of greater humanity and justice to the mentally maimed than prevailed before his day. He so amplified and emphasized the definition of Andrew Combe: "A prolonged departure without adequate external cause from the natural modes of thought, feeling and action of the individual," as to make it plain and effective in many celebrated cases of lunacy inquiry before American courts and juries. His clear-cut description of morbid mental character as shown in the Parish and Angell will cases, the Hinchman and Bernard Cangly cases, and the trials of Rogers and Winnemore won him undying forensic fame as a faultless psychiater in court, while his analysis of Shakespeare's delineations, his illustration of the insanity of distinguished writers and of King George III.; in short, every chapter in his contributions to mental pathology prove him to have been the peer in power of psychologic analysis of the mind diseased, of any alienist of his day. His treatise on mental hygiene for youth further confirms this opinion, and I had opportunity in his later lifetime to personally observe his clinical ability as a very Corypheus in practical psychiatry as I, as a guest, walked the corridors of Butler Hospital with him while he filled the place of my friend, Dr. Sawyer of Butler Hospital, then absent in Europe. Both are jewels in psychiatry's crown. Ray was the author of "The Propositions," a set of rules and regulations for the government of hospitals for the insane, which, like his little treatise on the good superintendent and the good attendant, were never equaled before and have not been surpassed since.

Since Ray, Galt, Stearns, Awl and Gray, Godding, Spitzka, Hammond, McLane Hamilton, Fisher, Webber and Folsom have made valuable contributions, also Storer and Mann, and I myself have added a few monographs, but none have surpassed or even equaled the great leader whose mortal remains lie buried in Greenwood, while immortal memories stretching over the world of psychologic science, center at his tomb.

Before passing on I stop to note the most philosophic treatise on pseudopia since "Dendy's Philosophy of Mystery," or "Brierre de Boismont's Hallucinations" appeared, and far more scientific, namely, "Visions: A Study of False Sight" (pseudopia), by Edward H. Clarke, M.D., of Boston, written, like the memoirs of General Grant, Napoleon and Thomas H. Benton, while fighting malignancy, marching remorselessly and resistlessly to inevitable victory. In this book, written in 1877 and dedicated to Dr. Oliver Wendell Holmes, the author's anatomic, physiologic and pathologic basis of cerebral visions still holds to a very considerable extent with the profession and though not wholly novel at the time, no work up to that date with which I am familiar, had so fully or so clearly presented the subject.

We go back now to an earlier date to find in neurologic annals the distinguished name of Dr. Amariah Brigham, first of Vermont, later and finally of New York, and his two treatises, the one on "Mental Cultivation and Excitement," in 1845, the other on "The Brain and Nerves," show how early and forcibly American attention was drawn to neurology as a proper and imperative study. In an inquiry of 227 pages, "Concerning the Diseases and Functions of the Brain, Spinal Cord and Nerves," published by George Adlard, New York, in 1840, by this author, is contained a great many valuable clinical contributions to psychiatry and neurology, which have not been duly credited to him. He was the first alienist to look upon masturbation in certain cases as the result and not the cause of insanity, contrary to Rush.

The power of expectant attention and self introversion is most intelligently presented by him under the head of "Effects of Mental Attention on Bodily Organs," giving clinical illustrations of dyspepsia, melancholia and fever thus induced and of cures effected. His original view of dyspepsia as a nervous breakdown, I believe to be the most tenable view of the subject in the face of extensive clinical observation, as I have elsewhere noted.[4] He noted cases of hysteria in the male and elucidated the subject, as well as of chorea, tetanus, hypochondriasis, delirium tremens, etc. His conceptions of the nature and causes of neuralgia were nearly up to the present date. He understood epilepsy about as well as we do today and enjoined that "the brain and nervous system of those who die of epilepsy should be examined with great care, and whenever opportunity presents should be compared with those who have never been affected with that disease." He had advanced knowledge respecting the relationship of the vagus nerve and sympathetic systems. Discussing a case of suicide in a case of recurrent delusional insanity, which, on postmortem examination, showed "upon the nervus vagus, or pneumogastric nerve, of the left side, just before the recurrent is given off, a fixed hard jagged body about the size of a kidney bean or small wart composed of calcareous matter," he says: "When we consider that the nervus vagus rises in the medulla oblongata, but is chiefly distributed to the great organs not under our control, and that it communicates with almost the whole of the ganglionic nerves, we may form some idea of the irritation and disturbance produced in the digestive, sanguiferous and sanguific organs by a jagged calcareous mass implanted, as it were, into one of the most important nerves of the great vital viscera!"[5] How like a modern neurologist he speaks! But hear him further. Concluding an article on the great sympathetic nerve and diseases and autopsic morbid appearances connected therewith, with regret at the paucity of knowledge of its functions, he says: "We know . . . enough to convince us that they (its functions) are important" and "we can not but lament its condition is so little regarded in disease and in postmortem examination."[6] Tilt could talk no better. He discusses focal lesions of the brain and of all of the cranial nerves in a most intelligent manner for his time; gives a case of traumatic aphasia without, of course, having a name for it, and a case of bullet wound of the corpus callosum from Hennan with apparent recovery, but subsequent death from a bout of drinking with the wounded soldier's comrades. But we can not follow this interesting pioneer in neurology further. From what we have thus far taken from this author we are well prepared for such up-to-date expressions as appear in the preface to Brigham on the brain, notwithstanding they were spoken fifty-seven years ago. "The study of the human brain yields in utility and dignity to no other. It is the study of the most important part of the organism, of that portion for which all the others seem to be created. It is of the highest philosophic interest from the connection of the nervous system with the manifestation of mental phenomena."

---

[4] Vide Address on Medicine, American Medical Association, at San Francisco, 1894.

"From the general diffusion of this system and its known uses we should expect it to have great influence in disease and that, as intelligence and mental cultivation, the excitement of the feelings and passions, all of which affect this system, increase, that an increase of nervous diseases and new affections of this system should be observed." And this we find to be true. Apoplexy, palsy, inflammation of the brain, dropsy of the head, insanity, etc., are far more common now than in past ages and are most observed in countries where there is the most mental excitement. We also now witness forms of nervous diseases or affections of the brain and nerves that were nearly unknown half a century since. Enjoining a more accurate knowledge of the anatomy of the brain and its connections, he regrets that "generally diseases of the nervous system are not thus investigated," and complains that "attempts to elucidate the diseases of the spinal marrow by autopsic examination are quite rare and those of the ganglionic system still more so." "Every one knows," he continues, "that certain symptoms indicate disease of the brain, or its membranes, or nerves, but until quite recently, and now almost generally, physicians rest satisfied with merely knowing that disease is located somewhere in the skull, but we should certainly strive to know more than this. . . Few physicians are satisfied with merely knowing that a patient has some disease within the abdomen or thorax; they seek to know what particular organ is affected and what tissue or portion of the organ is diseased. . . . We have but to pursue the same course as regards diseases of the nervous system," etc. "This field of investigation is indeed very great and will require for a long time many laborers, but ultimately, I apprehend, will richly reward those who cultivate it."

The object of his work, he tells his readers in his preface, "is to call attention of practitioners of medicine to the importance of the nervous system; and to persuade them to embrace every opportunity to study its functions and diseases," which have "vastly increased with the increase of civilization and now constitute a far greater proportion of the diseases of mankind than in past ages and consequently demand far more attention."

Here was the neurologic pathfinder who blazed the way through the unknown forests of neuriatry for an army with torches and banners whose bright lights have since illumined the world. By these early lights we now see why it is that American neurology has so many brilliant and sturdy devotees and contributors like its emblematic statue of Liberty, to enlighten the world. If nervousness is, as our neurologic cousins across the water assert, the American disease, it had American discoverers, and the name of George M. Beard is immortal as a later pathfinder in neurology and neuriatry. His untimely death was indeed a great loss to the world and that part of the world in which we delve.

His treatise supplemental to "Neurasthenia" entitled "American Nervousness," and the "Scientific Basis of Delusions" and other contributions which go to make up the pedestal of his fame, are noted elsewhere.

M. Gonzalez Echeverria, whose work on epilepsy with anatomico-pathologic notes, original plates and engravings, first appeared in 1870, had about as thorough a clinical knowledge of epilepsia as any writer of his time, and basing his views on clinical observation and the experiments of Kussmaul and Tenner, "that sudden arterial anemia of the brain, as also Faradization of the cervical sympathetic nerves which determines permanent spasms of the blood vessels, gives rise to epilepsy," he maintained that epileptic convulsions are likewise induced, as well as "when the blood rapidly assumes a venous character."

Kussmaul and Tenner's experiments, in addition to those of other physiologists, establish the chief share which the sympathitic has on the determination of spasms and confirm Brown-Sequard and Vander Kolk and *he* maintained that the seat of epilepsy "the *nodus epilepticus* is in the medulla oblongata, with a material modification in every case." The over-excited action of the "ganglionic cells of the medulla controlling the vasomotor elements and nutirtion," were to him the seat and cause, the invariable and necessary element, of the epileptic paroxysm which he says, "may well occur without muscular spasms." Notwithstanding the exception taken by Vander Kolk to Echeverria, "cerebral anemia is among the very initial phenomena of the epileptic paroxysm."

Though the exclusive medulla oblongata origination of epilepsy is not now tenable and cortex or Jacksonian epilepsy is a proven fact, yet the vasomotor spasm view of this author has not yet been overthrown and his "Discussion of the Modern Doctrines of Epilepsy" is still critical and classical in the light of further and later discovery.

---

[5] P. 222. [6] P. 197.

Next upon the scene appear in paths to American Neurologic glory William A. Hammond, Weir Mitchell, H. C. Wood, Seguin, E. C. Spitzka, McLane Hamilton, James G. Kiernan, Chas. K. Mills, J. J. Putnam, Isaac Ott, Charles L. Dana, R. W. Amidon, M. Allen Starr, J. K. Eskridge, S. V. Clevenger, B. Sachs, Daniel R. Brower, Harold N. Moyer, Frederick N. Peterson, William Fuller and a host of others whose names may come to us as we proceed, and their work appear in the supplement to this paper and in the future historian's pantheon of America's neurologic gods.

Hammond, by his indefatigable zeal and captivating style of writing, gave an impetus to neurologic medicine whose wave is still felt in the profession. In 1867, shortly after his retirement from the surgeon generalship of the United States army, he founded and for many years maintained the *Journal of Psychological Medicine and Medical Jurisprudence*, a high grade quarterly periodical which was promptly accorded and always held front rank in the literature of neurology.

In the second volume, the dynamometer and dynamograph are for the first time, in this country at least, illustrated and elaborately described by Dr. H. In this volume Hammond maintains that chlorosis is a disease of the nervous system. In this volume also appears a unique presentation of the subject of "Carnomania" by Charles F. Taylor; the "Microscopical Appearance of the Brain and Spinal Cord" by J. G. Webber of Boston; "Historical Considerations Concerning the Properties of the Roots of the Spinal Nerves" by Austin Flint, Jr.; Roberts Bartholow, then of Cincinnati, and E. C. Seguin have separate articles on "Aphasia;" T. Edwards Clark handles the subject of "Animal Magnetism;" Hammond, "The State of the Mind During Sleep;" "Organic Infantile Paralysis," S. Henry Dickson;" "The Legal Consequences of Insanity," Horatio R. Storer; "The Law of Rape, Suicide and Insanity," by T. Edwards Clark; Hammond, "Epilepsy Due to Cerebral Anemia;" Nathan Allen of Lowell, "The Law of Human Increase, or Population Based on Physiology and Psychology;" "Statistics of Opium poisoning" by Alonzo Calkins of New York; "An Improved Pocket Æsthesiometer" by Hammond, besides an interesting chronicle in each number of the world's contributions to psychiatry, neurophysiology and neurology. This ably conducted and invaluable journal was continued for years.

Hammond's classical works on "Diseases of the Nervous System," "Insanity," etc., are too familiar to the neurologic world to require elaborate portrayal here, even if we had the space and you the time for the record.

Hammond's early impress on American neurology, as it is upon the literature of medicine, is indelible. His original description of athetosis alone is an addition to neurologic discovery, as are Weir Mitchell's on "Erythromelalgia" and the cremaster reflex that have stood the crucial test; and I think I may likewise modestly claim something for the virile reflex and its clinical and medico-legal value when it shall have been further studied. The difficulty of eliciting it is its chief obstacle to acceptance, but it is an undoubted clinical fact of great value in diagnostic neurology.

Hammond inspired a host of younger men to follow his footsteps. In January, 1874, under his inspiration the first number of the *Chicago Journal of Nervous and Mental Diseases* was started by the lamented and talented J. S. Jewell and his able associate H. M. Bannister; the first article of the first volume being an original lecture on the "Pathology of the Vaso-motor Nervous System" by Jewell, who had produced the same at a lecture in the Chicago Medical College. These lectures were continued through this volume. The articles, selections and annotations were of a high order. This journal was temporarily suspended at the death of its talented and cultured senior editor, but soon revived again and brought out in New York, where it continues to appear as a monthly of no mean merit under the editorial management of Dr. Charles Henry Brown and an able corps of well-known collaborators.

In January, 1880, my own journal, the *Alienist and Neurologist*, first appeared in St. Louis. It has never missed an issue since its first number and we continue to do business at the old stand and on the same principles of progress; regarding a proper understanding of the nervous system, anatomic, psychiatric and neuriatric, as the chief end of man in medical research and practice.

Antedating all of these periodicals, we must not omit mention of that staid and valuable old neurologic periodical, limited in its scope, however, to the psychiatric side of neurologic medicine, the *American Journal of Insanity*, which, under the editorial management of Richard S. Dewey of Chicago, continues the good work so well begun over a half century ago. In its earlier issues may be found the records of American clinical and forensic psychiatry of most of the old masters, especially of the original thirteen who founded the Association of Superintendents of American Hospitals for the Insane, from which has descended the present American Medico-psychological Association. Their names were: Samuel B. Woodward of Connecticut, first president of the association and originator of the Hartford Retreat; Samuel White, of the same State, and late Professor of Obstetrics and Surgery in the Berkshire Medical Institute, founder in 1830 of a private institution for the insane on the Hudson, and president of the New York State Medical Society; Isaac Ray; Luther V. Bell, of New Hampshire; Charles H. Stedman, of Massachusetts, a graduate of Yale and Honorary of Harvard; John S. Butler, of Hartford; Amariah Brigham; Pliny Earle; Kirkbride; William M. Awl, of Pennsylvania; Francis T. Stribbling, of Virginia; John M. Galt, of Virginia; Nehemiah Cutter, of New Hampshire—all men who made their mark well for the welfare of the insane and the advancement of American alienism.

No country ever had so enthusiastic, united and powerful a phalanx to fight for the rights of the insane. Following in the footsteps of Chiarugi, Pinel, York and Tuke, they bravely fought the foes of psychologic advance to overwhelming defeat and won a lasting triumph of humanity and science in the treatment of American insane.

Weir Mitchell's work is likewise too familiar to us all to need recalling here. He is known out west as "rest cure" Mitchell, and "fat and blood" Mitchell, though he himself at the time he was so christened was as lank and lean as hungry Cassius. But his fame rests on more enduring laurels, though these were enough. His views of the cerebellum as a re-enforcing ganglion, first offered in 1869, have lately been reaffirmed by Italian physiologists.[6] Besides what I have already referred to his scientific, to say nothing of his literary work, beginning in 1852 with an investigation into the "Various Forms of Uric Acid Crystals and their Alterations in Highly Acid Urine," and not yet ended, we hope, in his instructive clinic lessons of the present year, is a rich heritage of inestimable value to America's and the world's contributions to medicine. Hysteria, mental aberration, sciatica, neuralgia, neuritis, sleep jerks, ataxia, headaches and apparitions, blood pressure, double consciousness, the reflexes and too many other subjects to here enumerate, make up a volume of titles alone for the instruction of the student of neurology that will perpetuate his name forever.

The elder John K. Mitchell, father of Weir, is claimed by the latter to have antedated Sir William Gull in the description of spinal arthropathies, and the present John K. Mitchell, grandson of the senior, is walking wisely in the footsteps of his father. His recent book, "Remote Injuries of Nerves," is a valuable presentation of the subject highly creditable to modern American neurology. The younger Mitchell has added something worth considering to the classic work of Bowlby to the study of section and injuries of nerves and made valuable contributions on ascending and migratory neuritis and the knowledge of contusions and commotions of nerves, and degeneration and regeneration thereof has been advanced in his recent work, "Remote Consequences of Injuries of Nerves."

No history of neurasthenia would be complete without record of the writings of my much esteemed friend, Dr. E. H. Van Deusen of Kalamazoo, Mich., whose observations on this subject made public in 1867, I called renewed attention to in the initial volume of my journal, the *Alienist and Neurologist*, in 1880. Dr. Van Deusen was at the time medical superintendent of the Michigan Asylum for the Insane, and under the caption, "Observations of a Form of Nervous Exhaustion (Neurasthenia) Culminating in Insanity," wrote as follows: "Our observations have led us to think that there is a disorder of the nervous system, the essential character of which is well expressed by the term given above, and so uniform in development and progress that it may with propriety be regarded as a distinct form of disease."

A reference to the article introducing the subject will show also the essayist's view on that subject.

Neither would the subject of inebriety be justly treated without reference to the many American contributions to its literature by Mason, Crothers, Wright and others. Dr. T. D. Crothers has contributed since 1875 over a hundred articles on this subject, his chief elucidations being of alcoholic trance states and the medico-legal aspects of inebriety.

Alcohol and drug addiction and their psychic and physical causes have been studied by Crothers, Mason, Matteson and many contributors for the *Journal of Inebriety*, a quarterly periodical which has long held the uncontested field as the only journal of the world devoted exclusively to this subject. While some of its editors' views have been regarded as too radical, others have undoubtedly been held as advanced. Its clinical records give it just claim to a prominent and permanent sharer in neurologic progress. Valuable contributions by Gurdon W. Russell, T. L. Wright, Mason, Crothers and others, may likewise be found in the earliest numbers of my own journal. Wright's Treatise on this subject had its inception in the earlier contributions to the *Alienist and Neurologist* as Geo. T. Stevens' later book on "Eye Strain in Nervous Diseases" did. In 1877 Stevens enucleated an eye-ball and cured a case of diabetes and in 1888 another for epileptiform disease with diabetes. Both recovered.[7] The subject of oculo-neural reflex irritation also first appeared in the (*vide supra*) *Alienist and Neurologist*.

The foundation of the American Medico-Psychological Association which was begun by the original thirteen as the Association of American Hospitals for the Insane and the organization of the American Neurological Society was the beginning of the diffusion of correct conceptions of mental and nervous diseases and their real clinical and medico-legal significance among the general profession and the people. This work has also been greatly promoted by the New York, Philadelphia and American Medico-legal Societies, and sections and societies of psychic research. The clinical lectures of E. C. Seguin gave the world new light on the spastic paralyses and paraplegia, the excellent work of Spitzka takes rank with that of Golgi and others abroad on the fine anatomy of the brain. While Sepilli was working on cerebral thermometry in Italy, Amidon and Carter Gray were engaged in the same work in New York and Bert Wilder has overwhelmed us with an almost entire recast of the nomenclature of cerebral anatomy, some of which has already and much more is destined to be finally accepted by anatomic cerebrology.[8]

The late contributions of William Fuller of Grand Rapids, Mich., to the objective study of course cerebral anatomy by his unequaled sectional models and book of plates, as well as his contributions to neurosurgery, tapping the lateral ventricles and exploration for cerebral abscess, the differentiation between coma of compression and reflex arteriole spasm coma, in 1897, his enunciation of the anemia theory of convulsions, his arteriole spasm theory of the treatment of cerebral convulsions and his cranial sections for certain forms of idiocy at an earlier date, certainly entitle him to honorable mention in any record of neurologic progress. He also maintains that keloid is of the nature of neuroma and caused by injury or disease of nerve endings, and he drained off the subarachnoid in a case of convulsions, embarrassed respiration and cerebro-spinal fever in 1880.

In 1879 Dr. C. H. Hughes read before the Missouri State Medical Association a paper entitled "A Clinical Inquiry into the Significance of Absent Patellar Tendon Reflex," showing at that early date that the knee phenomenon was absent in many cases other than locomotor ataxia. Subsequent or simultaneous observations of others, including Landon Carter Gray, Bannister, Erb, Westphal and Tschirjen, have confirmed the fact. The paper maintained that the diagnostic value of the patellar tendon reflex sign was rather in its having been lost in connection with other ataxic symptoms. Dr. Gray was the first to maintain that the nerves involved in the tendon reflex phenomenon belong to a variety not hitherto recognized, *viz.*: voluntary nerves with involuntary fibers distributed to voluntary muscles, while Gowers at the time objected to characterizing the phenomenon as peripheral-central. But it is quite probable that all voluntary muscle innervation has also latent involuntary nerve fiber tracts, and that the involuntary muscles have also latent voluntary fibers, else how are we to explain the phenomena of convulsions and the control of the heart in certain persons, as in the case of Colonel Townsend, who could at will arrest his, and the control of the ears, scrotum, etc., in others.

[7] See Alienist and Neurologist, 1, Vol. No. 1.

[8] The old world and ourselves may make wry faces at having to swallow the new nomenclature, as chemistry did a few decades ago, but I think we shall have to come to Wilder's terms, not all of them, but most of them in time. Wilder schemes than his [illegible] cable in science.

Peripheral nerve tissue is readily reproduced. Dr. S. Weir Mitchell, in speaking of the pathologic results of neuritis after injury to nerves, long ago noticed an enormous development of connective tissue elements, and Herdman has made some confirmatory observations the present year on nerve repair after injury. But the reproduction of brain substance has been doubted. Al. M. Vitzoy[9] (Bucharest) found in the brain of a monkey a new formation occupying the back part of the skull, after incision of the occipital lobes two years previously, which he proved to be nerve cells and neuroglia exactly comparable in appearance to those present in normal tissue. Theodore Simon, in the earlier editions of Virchow's *Archives*, reports some cases of what he denominates additional brain growth where new formations were found superincumbent upon the gray matter of the convolutions. In these new growths the gray and white matter were normal in their relations and proportions. But Dr. John B. Gray as early as 1875 (Tranactions of the New York Academy of Medicine) records two cases of reproduction of brain tissue after brain injury, the length of time in reparation of tissue corresponding with reparation of nerves after injuries. The brain was some twenty days in completing its structure and the convolutional character of the surfaces was distinctly marked.

The case of Phineas P. Gage, who had a part of his left brain destroyed by a premature quarry blast in Vermont, and the projection of a tamping iron through his head, Sept. 13, 1848, subsequently dying on a farm near San Francisco, May 20, 1861, is the most remarkable contribution to the subject of brain tolerance of violence and the possibility of brain repair on record. The iron that went through his head was a cylindric bar one and one-quarter inches in diameter, three feet seven inches in length and weighing thirteen and a quarter pounds. The bar tapered to a quarter of an inch and was chisel shaped at one end. It entered the brain in front of the left lower jaw, small end first, and out through the anterior-superior part of the left parietal, destroying the anterior part of the left hemisphere, thence through the corpus callosum anteriorly to the opposite side, extensively involving the margin of the right hemisphere, lacerating the anterior and middle lobes, falx and the longitudinal sinus. Gage recovered by the sixty-second day so that he walked a half mile, and by the seventy-third day so that he went home thirty miles away, the wound being closed on the one hundred and twentieth day. This man traveled, exhibited himself and the bar, acted as a hostler, drove a stage coach in South America and worked as a farm hand, dying of epileptic convulsions after an irregular life, in which intemperance played a part, but without paralysis or mental impairment, nearly thirteen years after; that is, he had neither paralysis nor mental impairment in the beginning. I was told by Dr. Warren or Dr. Bowditch, at the Boston General Hospital, by whose courtesy I saw the skull and tamping iron in 1868, that Gage was actually intellectually a brighter man after than before the accident. We all know that the skull of this remarkable case is now in the Warren Anatomical Museum and that the man was never lost sight of by American devotees of psychologic and neurologic science from the time of his remarkable recovery until head and history were secure in the depositories of science for the good of mankind. It will always be regretted that the brain could not have been examined microscopically. But psychiatry owes to Boston a debt of everlasting gratitude for what it has preserved in its archives of this case under such difficulties, as it likewise is indebted to the labors of C. E. Brown-Sequard for his contributions to the duality of the brain and the bromid treatment of epilepsy, though an English surgeon timidly antedated him before he took up his abode in Paris, and America antedates the world on the subject of brain and nerve repair and on the subject of neuritis. Kiernan, in 1882, and myself have contributed something to the literature of the duality of the hemisphere of the brain. I saw at the same time another remarkable case in the Boston General Hospital from Findlay, Ohio. I think it was a young man who had blown through his head, through the pontal region, a piece of gas piping about three-fourths of an inch in diameter.

Since Hammond, Allen McLane Hamilton, Landon Carter Gray, Wood, Dana, Ranney, M. Allan Starr and Dercum have given us treatises that compare with the best foreign authors. Dercum has marshaled in his treatise a galaxy of bright particular stars of the neurologic firmament, and Chas. K. Mills has in preparation a volume which we predict will be unsurpassed in any language. These, with Fuller's "Architecture of the Brain" already referred to, Shaw's "Diagnosis," Clevenger's and Moston's, would seem almost to have amply supplied the demand for neurologic literature without the many excellent translations. But the "Twentieth Century Practice," an international encyclopedia of modern medical science by leading authorities of Europe and America, edited by Thomas L. Stedman, M.D., New York city, is before us, and here is what an able reviewer[10] says of one of its volumes to the credit of American neurology:

"Volume ten is devoted to 'Diseases of the Nervous System.' With the exception of Dr. Féré of Paris, who furnishes articles on hysteria, epilepsy and the spasmodic neuroses, the contributors to this volume are all our own countrymen—the international element is less in evidence than in the preceding volume.

"Dr. Joseph Collins of New York has a long article of 300 pages on the important subject of diseases of the brain, and another on diseases of the meninges. Dr. B. Sachs of New York deals with tumors of the brain, and is sanguine enough to predict even far greater success in the diagnosis and surgical treatment of intracranial neoplasms during the next decade than has been achieved in the recent past. Dr. Charles L. Dana of New York writes on neurasthenia: Dr. H. T. Pershing of Denver on disorders of speech, and Dr. Sanger Brown of Chicago closes this volume of 859 pages with a short article on disorders of sleep."

---

[9] American Journal of Medical Sciences, October, [illegible].

[10] Boston Medical and Surgical Journal.

Treatises like those of Wilks, Ross. Maudsley, Bevin Lewis, Obersteiner, Hirsch, Erb, Westphal, Edinger, Mendel and others, with Charcot, Sepilli and a host of other German, French and Italian confrères, will ever be esteemed in America, but it is now plain that if cut off from them, American neurologic medicine would not starve for neurologic nutrition in its psychic centers.

But let us proceed. The first medico-legal differentiation between aphasia and aphasic insanity in this or any other country, so far as I can discover, was made by myself in 1879. The first contribution on the "Simulation of Insanity by the Insane" was also written by myself in 1876. In 1880 I wrote on nitrite of amyl in differential diagnosis, on reflex cardiac gangliopathy; in 1881 on consciousness in epilepsy, in 1882 on hyoscyamin and something new on the diagnosis of neuratrophia or neurasthenia. I proved the vasomotor contractile power of cephalic galvanization in 1883, maintained and established the curability of certain hitherto hopeless types of epilepsia and showed that the lesion of hemophilia and malarial hematuria is in the sympathetic system. While it is perhaps true that

> "To observations which ourselves do make,
> We grow more partial for the observer's sake,"

and that we do not wish our work, real or fancied, for the weal of the world forgotten, we must not overlook the fact that we have but meager space here for detail record of any one's work, so I pass over a few dozen of my own contributions to further notice those of your distinguished confrères in neurology, noting some of their work in the context and the remaining in an appendix.

Let us make a short trip to Chicago and dwell a few moments with that living neurologic and psychologic encyclopedia, James G. Kiernan. Next to Kohlbaum, he has thrown more light on katatonia than any other writer in the country. His first contribution on this subject appeared in 1877. And next on the study of Shakespeare's psychiatric characters. while his psychology and psychiatry of the prominent characters of history has not been exceeded by John C. Buchnill or William Ireland. His contributions to the study of psychology and psychiatry of genius, and the neurology as contradistinguished from the neuriatry of genius, have been numerous and instructive. Insanity in nearly all of its various forms and in many novel features has been described by his fountain pen of neurologic truth. In 1882 he wrote on the duality of the cerebral hemispheres.

The relation of insanity to crime has been instructively studied by Harold N. Moyer, Kiernan and others in this country: insanity proceeding from the colon by the former and by the lamented Jewell; the medical jurisprudence of railway surgery and shock by Moyer, Clevenger, Outten; the nervous sequelæ of influenza by Moyer, myself and others; a rare form of occupation neurosis by Moyer; also paranoia, nystagmus, acromegaly, infantile chorea, neuritis with knee jerks and nystagmus, exophthalmus with nephtis, etc.

In an inaugural thesis before the American Neurological Society, entitled "A Study of Nerve Cells and their Functions," Clevenger appears to have anticipated the later neuron theory (*vide* Chicago *Medical Review*, March 11, 1881, and "Comparative Physiology and Psychology," 1885). Fry has made some recent studies on the same subject. Clevenger's contributions are too numerous for detail here.

Frederick N. Peterson in 1879 made valuable studies on the posterior cerebral lobes in an inaugural thesis, and has kept up his search for new neurologic light steadily ever since. Among his later contributions are his prize essay on "Morbus Basedowii," the principles of craniometry, the study of muscular tremor, cataphoresis. electrothanesia, the colonization of epileptics, deformities of the hard palate in degenerates, the new phrenology, katatonia (with Dr. C. H. Langdon), chapters in Starr's special forms, Starr's children's diseases, Loomis', Bigelow's treatises, and the American text-book of diseases of the nervous system.

The "State Hospitals Bulletin" of New York, conducted by Wise, Brown and Reeves, has thrown a flood of new light over the pathway of our progress, Ira Van Giesen having made some startling revelations from the State Pathological Institute, of which he is director, on the relation of the auto-intoxications to neural diseases, which Nelson Teeter has followed up and elaborated on the autotoxic origin of epilepsy. Teeter's clinical studies on cerebral tumor and Courtney's on pachymeningitis also grace the first number of the first volume.

While trephining for cerebral pressure by fluid was first suggested abroad by T. Clay Shaw in 1889, and performed by Hamson Cripps in July of that year, it was done in this country on the following March by Wagner of Utica.

In 1891 Quincke first performed paracentesis spinalis for hydrocephalus. In May, 1896, Turner performed this operation for general paralysis, and in this country Dr. Warren L. Babcock in July of same year; and these bulletins contain a record of his work. Here, too. we find Hutchings following up the discovery of Huchard on cerebral meiophragias with valuable researches on this condition of arterio-sclerosis associated with certain mental symptoms.

In truth, these bulletins reveal a bewildering scope of work creditable to American clinical psychiatry and neurology, and we can not name all the works save in a bibliography. Here Somer's case of general paresis in its postmortem showing coincides with those of the West Riding Asylum's early reports, and Babcock's moral insanity confirms the contentions of our own earlier days.

Syphilitic hypochondriasis was presented in 1888 by Allen McLane Hamilton, and Carter Gray has lately added to the diagnostic signs of melancholia and intracranial syphilis, and Frank C. Hoyt of St. Joseph, Mo., pathologist to State Lunatic Asylum No. 2, gives us postmortem light on this subject.

Hugh T. Patrick, who is no more of a saint than my friend who dreams over the hookah, though he hails from the saintly city of Chicago, maintains that he has knocked out the Bryson symptom in exophthalmic goiter, showing by a study of forty cases that the diminished chest expansion frequently found in Graves's disease is in no sense pathognomonic, but is simply an expression of the general myelasthenia which he maintains is always present in this affection. An experimental and anatomic study of the course and destination of Gowers' tract by this writer, established the fact the Gowers' antero-lateral tract extends as a separate bundle as high as the corpora quadrigemina and then passes in a retrograde direction to the middle lobe of the cerebellum.

The intimate relation between asthenic and bulbar paralysis and poliomyelitis, has been shown by this author in a recent report of a case of so-called polioencephalitis superior and inferior with a careful microscope. Dr. Patrick's studies in trunk anesthesia in locomotor ataxia and syringo-myelia reveals a novelty in symptomatology and he maintains that "spinal irritation" is psychic and not located in the spine.

Frank G. Lydston and Eugene S. Talbot have made valuable contributions to the study of the stigma of degeneration especially in criminology, including regicides, inebriates and aristocratic degenerates. Chicago is a good place in which to study criminology and degeneracy and these gentlemen are well qualified for the work.

M. Allen Starr's atlas of the nerve cells, with the coöperation of Strong and Leaming, though published abroad, is highly creditable, like Fuller's plates and casts, to American neurologic industry, ability and ingenuity. Starr's work on brain surgery has been complimented by translation into the German and French languages. His contribution to the study of tumors of the spinal cord, 1895, and diagnosis of cerebral abscess, 1897, are valuable additions to cerebrology and spinology.

We are indebted to Daniel R. Brower of Chicago, for a new surface thermometer, and many studies in medico-legal and traumatic insanity, electro-therapy and spinal neurosis; to Brower, Andrews and Hughes for separate clinical studies of hyoscyamin; to Brower, Clevenger, Kiernan and many others, for records of traumatic insanity; to Brown for the case of Mark Gray (concealed insanity) and Pendergast as a paranoiac, and too many other records and monographs for our space.

Progress in the knowledge of the localization of sensations has been made in this country, especially through the studies of Dr. Charles L. Dana, and the diagnosis of intra-cranial hemorrhage and acute softening, vertigo in temporal lobe lesions; apoplexy, the apoplectic pulse, the cause of perforating necrosis of the spinal cord, its continued sclerosis, the pathology of chorea and paralysis agitans, and studies in alcoholism, acromegaly and the pathologic anatomy of tic douloureux, besides his text book on nervous diseases, now going into the fourth edition, which has features unexcelled in any book published abroad.

The.literature of multiple neuritis, paramyo-clonus multiplex, the neuron conception of the nervous system, chorea and Raynaud's disease have been written upon by Fry, of St. Louis. Bauduy has given us a book that ought to be revised; Bremer has added to the literature of microscopic blood states in disease, and Shaw's diagnostic neurology and contributions to morbus Thomsenii, are valuable additions to the literature of neurology, and my own work which appears mainly in my journal, the *Alienist and Neurologist*, founded in 1880, offer to your critical consideration. If I have accomplished but little it is not because my intentions have not been good. In addition to what has already been cursorily referred to, I claim the introduction of chloral hydrate per rectum in puerperal eclampsia, infantile convulsions and obstetric practice, besides early articles on the dual action and vicarious functions of the cerebral hemispheres and lobes of the brain, aphasia, hyoscyamin in psychiatry, moral and other forms, and the definition of insanity. If we take the wings of the morning and fly to the uttermost parts of the earth we shall find the neurologist there, so rapid has been the progress of neurology within the short time since it began to take rank as a medical specialty, almost within the average life of a generation of men. But we read and go beyond the confines of our own country to be satiated with the richness of neurologic contributions. An examination of the psychiatric and neuriatric bibliography here appended would make one feel, after what we have thus far gone over, like "gnawing a file and fleeing unto the mountains of Hepsidam" for rest, "where the lion roareth and the whangdoodle mourneth" for our diversion, but we will stop awhile at the Rockies and here we find Pershing perched on the heights of Denver, Thombs lower down in Pueblo, and Jeremiah T. Eskridge, the lion of the tribe of Judah, who went out to Denver with one lung and developed a voice that has been heard in highest and strongest neurologic notes around the world. He has been so active there that the festive bacillus tuberculosis could not find further lodgment on his never-resting cerebral anatomy. I have before me a record of 103 contributions to the literature embracing every aspect of neurologic inquiry from diagnosis, pathology, physiology and treatment to the neural therapy of climate. His articles on retro anterograde amnesia, temporary abulic agraphia, symptoms of speech disturbances as aids in cerebral localization, on brain tumors and glioma, and chapters on insanity and feigned diseases, the latter in the "American System of Medical Jurisprudence," have commanded our attention.

Since American medical literature had its birth here and since we started our incursion here it is mete that we return. There are neurologic giants in Philadelphia whose measurements we have not yet taken. The contributions of Dr. James H. Lloyd embrace brain tumors, syringomyelia, diseases of occupations, the spinal cord in pernicious anemia, Friedrich's ataxia, etc. And here are some of the blows Chas. K. Mills has struck in opening the way to the high pinnacle on which American neurology stands today:

"The Relation of Infectious Processes to Mental Disease," *American Journal of the Medical Sciences*, November, 1894; articles in an "American Text-book of Diseases of Children," edited by Louis Starr; "The Naming Center," *Journal of Nervous and Mental Disease*, January, 1895; "The Localization of Lesions in the Pons and Pre-oblongata," *International Clinics*, vol. iii, fifth series, 1895; "Some Phases of Syphilis of the Brain," *Medical News*, vol. lxvii, 1895, p. 606; "The Diagnosis of Intracranial Tumors," *University Medical Magazine*, March 18, 1896; "Mistakes in Neurological Diagnosis," *Philadelphia Polyclinic*, July 25 and Aug. 1, 1896; "A Case of Cerebral Abscess Situated at the Posterior Part of the External Capsule," with Dr. William G. Spiller, *Journal of Nervous and Mental Disease*, September, 1896; "Cases of Aphasia Illustrating Especially Disorders of Pantomime," *Philadelphia Hospital Reports*, vol. iii, 1896; "A Series of Reports of Cases from the Neurological Department," *Philadelphia Hospital Reports*, vol. iii, 1896; and "Treatment of Diseases of the Brain," in an American Text-book of Applied Therapeutics edited by J. C. Wilson, 1896.

Dr. Mills has nearly completed the first part of a "Practical Treatise on the Nervous System and its Diseases," a volume of about 1,000 pages, which will be issued by J. B. Lippincott Company of Philadelphia, about the first of October of the present year, and every American neurologist will be proud of it. He is the author of too many neurologic monographs to be here enumerated; his articles, clinical and pathologic, include reports on many cases of brain tumor; numerous clinical lectures and reports on the affections of the nervous system; articles on hypnotism; medico-legal papers; the Toner "Lecture on Mental Overwork and Premature Disease Among Public and Professional Men," published by the Smithsonian Institution; articles on hysteria, hystero-epilepsy, catalepsy and ecstacy, in the "American System of Practical Medicine;" and in the same work, "Tumors of the Brain and its Envelopes" (with Dr. James H. Lloyd); numerous reports on cases of insanity and papers on cerebral and spinal localization, and "Cerebral Localization in its Practical Relations."

Besides these names those of Spiller and Marineso come to me, but a record of the work must now be deferred.

As I close this report I note that the leading articles in many of the latest issues of the leading journals of the country are on advanced neurologic subjects. Lewellys F. Barker in the *New York Medical Journal*, continues his interesting contributions on the nervous system and its constituent neurons; Allan Bonar in the *Record*, gives us new light on many disturbances in locomotor ataxia, and Henry Hun, who has contributed much in years gone by, gives an instructive study of analgesia, thermic anesthesia and ataxia, from focal softening in the medulla oblongata and cerebellum due to occlusion of the left inferior posterior cerebellar artery, further enlightening us on the course of the sensory and coordinating tracts in the medulla, and Henry M. Lyman of Chicago, in the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION for May 22d, elaborates the subject of nervous dyspepsia with proofs of the position taken on this subject (though he does not name them as such) by Brigham seventy years ago and referred to in the beginning of this essay.

During the past year there has appeared in my journal alone advanced neurologic articles on the following subjects: "The Anastomoses Between the Spinal Accessory and the Vagus," by Drs. D. Mirto and E. Pusateri; "Some Current Errors Regarding Insanity," by Dr. Arthur E. Mink; "A Case of Chronic Chorea, with Pathologic Changes Similar to those of General Paresis," by Dr. E. D. Bondurant; "A Note on the Treatment of Sexual Inversion," by Havelock Ellis; "The Advancement of Psychiatry in America and the Relation of Psychiatry to General Medicine," by Dr. Edward Cowles; "Abuse of the Bromides," by Dr. Harriet C. B. Alexander; "An Ataxic Paranoiac of Genius," by Dr. J. G. Kiernan; "Hysterical Analgesia," by Dr. C. C. Hersman; "State Care and State Maintenance for the Dependent Insane in the State of New York," by Dr. Carlos F. McDonald; "Nervous Shock and Disease of the Nervous System as a Cause of Pernicious Anemia," by Dr. James B. Herrick; "Differential Diagnosis of Insanity," by Dr. C. B. Burr; "Observations on the Histologic Development of the Cerebellar Cortex in Relation to the Faculty of Locomotion," by Dr. Aurelio Lui; "Scrivener's Palsy not Solely Pen Fatigue," by Dr. C. H. Hughes; "Are Americans Degenerates?" by Dr. Jas. G. Kiernan; "Sociology and the Realistic Novel," by Dr. Ingeborg Taustrom; "The Surface Thermometry of the Head in Diseases of the Brain," by G. W. McCaskey; "Syphilis as an Etiologic Factor in the Production of Locomotor Ataxia," by Dr. C. Travis Drennen; "The Psycho-Neural Factor in Medical Practice," by Dr. C. H. Hughes; "Psychical Hermaphroditism," by Dr. William Lee Howard; "Preputial Reflex Epileptiform Convulsions, with Report of a Case," by Dr. Alex L. Hodgdon; "Intemperance, Consanguine Marriages and Educational Overpressure, as Factors in the Genesis of Nerve Disease and Degeneration of the Race," by Sir Frederick Bateman, M.D.; "What is Meningitis?" by Dr. W. S. Christopher; "The Case of Sturgeon Young, a Question of Hypnotic Injury and Death," by Clark Bell, Esq.; "Encephalitic and Late Epilepsy," by Dr. J. G. Kiernan; "Psychoses of Old Age," by Harriet C. B. Alexander; "The Auto-toxic Origin of Epilepsy," by Dr J. Nelson Teeter; "Insane Heredity," Dr. H. P. Stearns; "Analgesia of the Ulnar Nerve in the Insane," by Dr. Arrigo Giannone; "Report of a case of Brain Syphilis Heroically Treated with Mercury, Followed by a Mercurial Neuritis and Recovery," by Dr. William C. Krauss; "Interaction of Somatic and Psychic Disorder," by Dr. James G. Kiernan; "Imperiative Conceptions," Dr. C. H. Hughes: "Defence of Modern Psychiatry," Dr. Wm. Hirsch; "Cyclone Neuroses," Dr. C. H. Hughes; and the Effect of Extirpation of the Parathyroid Glands," by Prof. G. Vassale and Dr. F. General; while the list for the past ten years is a complete record of neurologic progress.

It is thus that American neurology and psychiatry moves up to the mountain top. If you do not concede that it is already there, you see we are getting there. The labors of the past three decades, as well as the work of the pioneers, have won for us a place at least beside our worthy brothers abroad in the world's neurologic progress. We at least are lending a helping hand, of which we need not be ashamed, in making its history. We are moving up with the world and moving the world up with us.

NOTE—The author wishing to make the report complete would be obliged for further facts with accurate bibliographic references.

SOME OBSERVATIONS AND EXPERIENCE IN THE TREATMENT OF EPILEPSY ACCORDING TO THE METHOD SUGGESTED BY DR. FELIX VON NIEMEYER.

Presented to the Section on Practice of Medicine at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, June 1-4, 1897.

BY MATTHEW WOODS, M.D.
PHILADELPHIA, PA.

So much has been said and done within the past few years in attempted elucidation and cure of that complex series of phenomena commonly known as epilepsy or "fits," that the preparation of another paper on the subject might be deemed an impertinence, but for the fact that the disease and its treatment, judging from printed current opinion on the matter, is still as much of a problem as it was twenty years ago, and that the treatment I am about to elucidate produces better results than that of any treatment with which I am acquainted.

It is not the intention of this paper, nor is it at all necessary to my purpose to discuss the cause and nature of the disease—a sort of "Pigrogromitus of the Vapians" among diseases, no one seeming to know who or what they were—so of epilepsy. The old theories are familiar enough, yet so little still is known of its etiology and pathology, that correct classification of its various forms is almost impossible. The familiar terms, *grand mal*, *petit mal*, traumatic, central, idiopathic, peripheral, congenital, laryngeal, gastric, Jacksonian, post-paralytic, hereditary, acquired, imbecilic, genito-neuropathic, senile, nocturnal and the like, *ad infinitum*, are mere pedantries of nomenclature bearing but slight relation to its causation factors and throwing no light upon the origin of the disease. One of the many merits of the treatment, according to the effective way suggested by Niemeyer, consists in the fact that, combined with various adjuncts, it is about equally efficacious in traumatic and non-traumatic epilepsy, in the variety due to organic disease where the spasm is but a symptom, and also in what may be called true epilepsy, where, as far as we know, the convulsion *is* the disease.

It is not likely that any one is able to tell much that is new about the malady, except perhaps a few of the less conservative of surgeons who, by certain brilliant work and at infinite pains, have shown, as it would seem, the possibility of curing or relieving certain cases by certain surgical operations on the brain, but unfortunately at such a risk, that it seems a question if the rather meager results were sufficient justification for the great danger.

And yet the frequent failure of operation on the brain for the cure of otherwise incurable epilepsy, is not an argument against the operation itself, but rather a confession of the inadequacy of our knowledge of its pathology to explain its phenomena and characteristics. Surgical operations on other parts of the body have been a benefit to epilepsy, the cure probably being due to shock, just as shock will sometimes induce an epileptic attack, and I am convinced that the operation on the brain would have more frequently relieved the malady, if it had not been for the many dangers involved in the operation itself.

The normal contents of the cranium completely fill, we are told, the cranial cavity. Any foreign material, therefore, entering or developing in this cavity, such as tumors, projection of bone from a depression or fracture consequent upon a blow, extravasated blood, exudation of cicatricial tissue, accumulation of pus, lymph or serum, necessarily diminishes the containing capacity of the calvarium in proportion to their bulk, and consequently destroys the equilibrium between the brain and spinal cord. When an epilepsy therefore is known to be due to this sort of pressure, and there is no other remedy, and the last state of the man is not likely to be worse than the first, in consequence of the operation, it might seem as if an attempt should be made to remove the cause.

But are we ever sure that epilepsy is due to mere pressure alone, and that removal of the apparent cause, even when such a procedure is comparatively safe, will leave the patient well? Is there no foundation for the theory that epilepsy is a habit to be cured by moral suasion, diet and medicine, rather than by the knife.

Men have had tumors of the brain without epilepsy. Cranial exostoses consequent upon specific disease have existed without fits; patients with exceedingly thick skulls, a thickness not congenital and consequently diminishing the normal containing capacity of the cranium, are not necessarily epileptics. Depressions of the skull due to unskilful use of obstetric forceps and other accidents, such, for example, as a crowbar going through the brain, as is well known, are not invariably the cause of fits, while men with sound heads and free from depressions are sometimes victims of the disease.

Lord Byron, whose brain was so large in proportion to the cranium that the mental activity consequent upon composition caused pain, was not an epileptic, while Cæsar, Hannibal, Mohammed, Charlemagne, Napoleon, with none of the stigmata of degeneracy, at least as far as sculpture and painting have recorded them, evidently were at the same time hydrocephalic, and other idiots with enormously distended crania, and nothing much in them but water, are often subjects of epileptic spasm.

It would thus seem that the presence of certain conjectural causes in the brain are not in themselves sufficient to justify operative procedure when the danger of removal is so great.

I am thus particular to mention the surgical treatment of this malady, first, because that in the modified Niemeyer treatment I have been using so many years with such gratifying success, surgery sometimes forms an exceedingly important adjunct to the treatment by drugs, and, secondly, because too much importance has been attached to the brain as the seat of epilepsy, and pressure on the brain as its cause.

The Briggs case is one in point. The patient, an epileptic, had a depression of the cranium due to fracture and at the same time a tibia requiring surgical aid. "The surgeon first wisely operated on the shin-bone, leaving the skull, the more likely cause of the disease, untouched." For five years after the patient had not had an attack of epilepsy. An experience which might mean that in this case the seat of the disease was the shin, but it might imply also that *shock* had something to do in modifying that excessive reflex excitability, perhaps the principal medium of seizure, and that on that account, not because the operation was done on any particular place, the cure was effected.

The seat of epilepsy may be anywhere, perhaps there are some parts more frequently its site than others, and any treatment not recognizing its versatility in the matter of starting point, must often fail. Its origin may be the cerebellum, the convolutions of the brain, disease or injury of the cerbro-spinal centers or of their meninges. Its origin may be in the mucous membrane of the bowels, the stomach, the sole of the foot, the finger, the os uteri, or any peripheral or central part of the nervous apparatus where an irritant may exist, and if there is essential analogy between man and the lower animals, which the writer decidedly doubts, to justify conclusions beneficial to man on observations made on these sometimes lower creatures, we might be led to believe it possible for epilepsy to be induced by simple friction of the skin covering the ribs, and even by the swallowing of such a usually innocuous fluid as common writing ink.

We once had a maltese cat that developed unmistakable petit mal, epilepsia meteor, that is to say, loss of consciousness with the muscular contractions limited to certain sets of muscles, by merely stroking her sides; and a tame raven, a resident of our home and constant companion for a year, would be seized with a complete epileptic attack, epilepsia gravior, immediately after drinking ink, of which he was fond. In the raven's attacks all the symptoms of grand mal (except pallor) appeared in their natural order, including the "epiletic cry," in this case a croak, universal clonic convulsions lasting however only a few minutes, then cessation of the fit, coma, apparent fatigue and sometimes sleep, after which he would remain entirely well until he indulged in another drink of ink. I have allowed the bird to thus contract as many as three fits a day to gratify the scientific and idle amusement of friends, but finally stopped it because of apparent cruelty.

A dose of quinin given to a patient being cured by the proper administration of bromid of potassium, will bring on an attack, so also will a large dose of the bromid itself not sufficiently diluted in water. The administration of tinct. muriate of iron and of the scales in solution of the pyrophosphate of iron, will cause the return of epilepsy after the disease has been apparently cured.

The pain in the back so frequently complained of in anemia, and which our laparotomy friends usually ascribe to some obliquity of that modern scapegoat, the over-vilified womb and its unfortunate appendages, is perhaps mainly due to gastric spasm caused by undigested food, occasionally to uterine and ovarian disturbance acting in a reflex manner.

This hyperkinesis or abnormal motor activity of the muscular tissue of the digestive organs due to vicious diet is, I believe, a much neglected cause of epilepsy. Nocturnal attacks are frequently brought about by an undigested supper; and abuse of the digestive organs, the cause of so many other disorders, is perhaps largely to blame for epilepsy.

I have seen epilepsy cease with the cure of an endometritis, also twice with the repair of a lacerated os. I also saw a case apparently cured by an operation for a congenital epispadias, the operation an adjunct, like the above, to the Niemeyer treatment. The epispadias likely having but little to do with the epilepsy since it preceded it a number of years, the shock of the operation or the impression made on the mind by preparation for the operation so altering the excessive reflex power—evidently the cause of epilepsy—that the seizures ceased. I have also had an inveterate case of the disorder, one but slightly benefited by drug treatment, cured by having her hand so charred in a frying pan that it had to be amputated, after which she had no more attacks of epilepsy up to her death, which occurred four years subsequent from consumption.

I mention these experiences because to the lessons they have taught me in connection with the persistent administration of bromid of potassium in gradually increasing doses and in large quantities of water, the two conditions insisted upon by Niemeyer, I may ascribe the success I have had in the manage of this popularly supposed incurable disease.

I am convinced that the failure of this drug in the hands of so many physicians to cure most cases of epilepsy, and help all, except cases where there is congenital deformity, is due to the lack of persistence in its administration, to not recognizing the necessity of giving it largely diluted in water and according to a regularly graded increase in the quantity prescribed, and also because I am convinced that the failure of the drug in the hands of so many is due, not to its inefficiency, but rather to its improper administration—the importance of its dilution in large quantities of water not being recognized. Even such a one as Brown-Séquard is so careless as to say, in talking of epilepsy: Give 20 or 60 grains of bromid of potassium four times daily, as the case may be, omitting to mention the quantity of menstruum, not apparently knowing that the salt will bring on the attack, if given in concentrated solution, and that its efficacy in causing cure and amelioration is due to the attenuation in water that facilitates endosmosis and causes a non-irritating assimilation.

The amount given depends entirely on the severity and frequency of the attacks, from 10 to 60 or 90 grains from one to four times daily. The treatment should be continued for at least a year after the cessation of convulsions and in prescribing this drug it should be remembered that a faulty administration will bring about a recurrence of the attacks.

In addition to the treatment by the drug, resort to the surgeon should be had as occasion requires. Lacerations of the os and other ills of the male or female genitalia should be remedied; constriction of the prepuce in epileptics ought to be corrected; constipation should not be allowed to exist; difficult menstruation cured; suspicious cicatrices should be excised; indigestion should be avoided; the adoption of a suitable dietary is of the greatest importance, allowing but a limited quantity of animal food and but once daily. Epileptics ought to be employed out of doors when possible, and in employment bringing a reward. Distension of the stomach by undigested, fermenting food and impaction of the bowels are a prolific cause of nocturnal attacks. An important point in the treatment of the disease is attention to the mouth, as deformities of the palate, alveolar abscesses, necrosis and exfoliation of bone are rather frequent and demand care. All the natural functions should be carefully protected from abuse.

By attending carefully to the above details and others less important perhaps, that my limit precludes me from mentioning and by giving the drug strictly in the way I have indicated, joy, hope and health may be restored to many so-called incurable epileptics, at present abandoned to despair, and many whose existence consists merely of suspense and unconsciousness may be rescued to lives of useful industry, and protected from attacks against which they suppose medicine can oppose no barrier.

DISCUSSION.

Dr. H. A. **West** of Galveston, Texas—Just before I left Texas I saw a case of about the severest petit mal in a child which ever came under my observation, and I wish to refer to some unusual reflexes in that case. The child had a very long prepuce which I desired to amputate, but the parents would not allow it. In addition it had a persistent and long continued hemorrhage from the bowel. Thinking that this might have had something to do with the epilepsy, I directed the use of a solution of subsulphate of iron in the rectum, and also gave bromid of sodium and sulphate of codein. The father told me that the hemorrhage subsided and the number of epileptic attacks was reduced one-fourth or one third. It is evident the reflex disturbances had to do with the epilepsy in that case.

A CASE OF RENAL TUBERCULOSIS.

Presented to the Section on Practice of Medicine, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1–4, 1897.

BY J. DUTTON STEELE, M.D.
PHILADELPHIA, PA.

The following case occurred in the wards of Dr. Joseph Hearn in the Philadelphia Hospital. I am indebted to him for the clinical history.

L. H., 23 years of age, a native of Ireland, white and married. There is no tubercular family history. She was admitted in October 1896. The patient had measles in childhood. Influenza five years ago which left her with a "weak right side." In January 1896 she was delivered of a six months fetus and since that time has been confined to bed continually. She has become much emaciated and has a profuse diarrhea. Examination of abdomen shows a large mass the size of a baby's head, in the right lumbar region. This is movable, and the skin is not adherent. The tumor is not painful except on deep pressure. A slightly tympanic note is heard in percussion over this mass. There is marked edema posteriorly in the lumbar region on the right side, extending up along the thoracic wall. The tumor appears to be distinct from the liver. There is no jaundice. There is no pain in the lumbar region. Micturition is frequent and sometimes painful. Urine: albumin $\frac{3}{4}$ by volume. There is much pus, no casts and no blood.

She was transferred to the surgical wards for operation, but this was deemed unadvisable. Her temperature then was 101 degrees, but soon fell to normal and remained subnormal until death. Her breathing was so shallow that physical examination was impossible. Now complains of some pain in the tumor. Is having many large green liquid stools. Examination of urine just before death showed albumin, pus, casts, but no blood. She died October 26.

The autopsy was made by the writer at the Philadelphia Hospital twenty hours after death. The peritoneal cavity is normal except that the liver is pushed forward and barely reaches to the costal margin. This is caused by a large tumor lying behind the peritoneum in the right lumbar region. The pleural sacs each contain a small amount of clear fluid. There is thickening of the pleura and adhesions at each apex. The upper lobes of both lungs show considerable consolidation at the upper portion. This is apparently due to a pneumonic process with scattered areas of caseous degeneration, especially about the bronchi. Considerable pus flows from these tubes on section and they contain caseous plugs. At the apex of the right lung is a cavity filled with purulent material. The left kidney is swollen and tense. The capsule strips readily, the cortex is swollen and of a green color, and the pyramids are congested. The pelvis and ureter are normal. The right kidney is found to constitute the tumor mentioned above. It is 25 cm. in length, 18 cm. broad and 15 cm. thick. The organ is surrounded by a considerable amount of fat that appears normal. On section the kidney is found to be extensively degenerated. The capsule is thickened and firmly adherent. The cortex measures 3 cm. in width, is dense and hard and of a chalky white color with numerous spots of extensive cheesy degeneration. The pyramids are represented by cone shaped masses, with central cores of cheesy material which empty into the pelvis which is filled with pus and caseous debris. The wall of the cones are dense and white; the walls of the pelvis are extensively infiltrated and its mucous membrane is ulcerated.

Microscopic examination of the right kidney showed hardly a trace of kidney substance. The capsule was greatly thickened and there was an increase of connective tissue in the walls of the masses that represented the pyramids. Around the margin of the degenerated area were collections of round and epithelioidal cells and occasionally giant cells. A number of sections were stained for the tubercle bacillus but without success. However, the diagnosis of tuberculosis was made upon the characteristic picture presented by the collection of cells, associated with the extensive degeneration.

The wall of the ureter is also much thickened. This infiltration extends downward along the whole length of the tube and involves the bladder wall around the orifice of the ureter. The epithelium from the pelvis to the bladder is degenerated and replaced by caseous material, but the lumen does not seem to be obstructed. The epithelium of the bladder has apparently entirely escaped the inflammatory process.

The internal genitalia are perfectly normal. The lymphoid tissue throughout the body is apparently entirely normal. Nothing else of interest is found in the body.

Section of the left kidney revealed much fatty degeneration and chronic parenchymatous nephritis.

After a study of numerous cases reported in the literature of the subject, it seems possible to make three divisions of tuberculosis of the kidney.

1. That which occurs as a part of a general eruption of tubercle, either as a manifestation of acute primary miliary tuberculosis, or as the terminal stage of tuberculosis elsewhere in the body. This condition can not be considered to be more uncommon in the kidneys than in the other abdominal viscera.

2. In the so-called primary renal tuberculosis, the process either manifests itself in the kidney alone or this organ is undoubtedly the primary focus. This form may be either of the miliary or of the chronic caseous varieties.

3. A form in which the priority of the process in the kidney must be doubted, but in which the disease manifests itself more intensely here than elsewhere. It is associated with foci of tuberculosis in other parts of the body, apparently most often in the bronchial glands, bones or lungs. Under this division must be classed most of the cases of urogenital tuberculosis that have furnished so much discussion concerning their pathogenesis. The difficulty of accurately determining the primary seat of the disease, even in those cases formerly classed as primary in the kidney, is much increased by the possibility of there being some obscure focus of the disease in the body that escapes any but the most careful observation at the postmortem examination—a fact whose importance has been unrecognized until the past decade. Tuberculosis may exist, unsuspected, in the various lymphoid tissues, as the bronchial glands or as lately shown by Dieulafoy and Krückmann in the tonsils.

The authorities on the subjects unite in the statement that the process when once started in the kidney is extremely rapid, and it could only be by most rigid clinical study that it could be determined whether, for instance, pulmonary or renal symptoms were the first to occur.

Senator, in Nothnagel's system, who may be considered to represent the most recent ideas on the subject, doubts whether a strictly primary renal tuberculosis ever exists; but would put all cases under the third division that I have made. He is supported in this view by Steinthal.

Age and sex appear to be predisposing factors in the causation of the disease.

All authorities state that the condition is much more common in adult life than in childhood. Carr found but two instances in 120 autopsies upon children; 16 per cent. of Facklam's cases occurred under 20 years. The disease is very rare in infancy.

Males are affected about twice as often as females as shown by the statistics of Ebstein and Roberts. Osler, Rosentein, Senator and Birsch-Hirschfeld also state that the disease is more frequent in the male sex. However in Facklam's series of 106 cases there were 79 females. Hamill's list gives three times as many boys as girls.

The condition almost invariably commences as a one-sided affection, and in about one-half of the cases the other kidney is involved before death. This furnishes an argument for early operation. The disease does not appear to show any tendency to affect one side oftener than the other. The miliary form commences in the cortex, and the chronic in the medulla. The first may lead to extensive caseous degeneration, but the chronic variety is the one that produces the most extensive necrosis. Occasionally the process commences in the pelvis but usually this escapes until the later stages. The diagnosis from examination of the urine is often difficult as with the pelvis intact the discharge of cheesy material and tubercle bacilli may be entirely prevented. The ureter is usually affected. Its walls are thickened and its epithelium degenerates with the formation of ulcers. The mucous membrane of the bladder very often escapes but its wall is thickened and there are often superficial ulcers upon the trigone. The tubercle bacillus may be found in the tissues in the earlier stages, but at the autopsy the process is commonly too far advanced.

When the kidney is alone affected, most authorities consider the process to be one of hematogenous infection. The best explanation for the presence of the bacilli in the blood stream in the purely primary form, if such exist, is that the microbes have entered through the mucous membranes of the intestinal or respiratory tract without lesion, or in other words by cryptogenic infection. But, after study of a number of reported cases, the writer is satisfied that there is often a cheesy lymph gland at the root of the lung or in the mesentery, that is the means of entrance, for the bacillus to the general circulation.
